where the overall factor A is independent of the temperature T and the scattering geometry, ω_M is the magnon frequency, and $n_M=[\exp(\hbar\omega_M/k_BT)-1]^{-1}$ is the corresponding Bose factor. The quantities F_{in} and F_{out} refer to the in-phase and out-of-phase contributions, respectively, to the scattering from the two sublattices of the antiferromagnet. Their explicit expressions are given in Ref. 1 and include the effects of a magneto-optic coupling that is quadratic in the spin operators as well as the usual linear magneto-optical coupling.[1,4] The quadratic magneto-optical coupling is known to be important in another rutile-structure antiferromagnet[4,5] FeF_2, and it is of interest to determine its effect in MnF_2. The possibility of an out-of-phase term in I_S arises because the two sublattices in FeF_2 are not equivalent (due to the coordination of the F^- ions). Hence, the theoretical model involves four magneto-optical coefficients that are independent of temperature and light scattering geometry. Following Ref. 1, these are denoted by K_+ and G_+ for the linear and quadratic magneto-optical coupling for in-phase scattering, while K_- and G_- are the corresponding coefficients for out-of-phase scattering.

The expression for the anti-Stokes intensity I_{AS} is similar to Eq. (1) provided the factor (n_M+1) is replaced by n_M. Also F_{in} and F_{out} are replaced by $\tilde{F}_{in}$ and $\tilde{F}_{out}$, respectively, obtained by making the substitutions[4] $K_+\rightarrow -K_+$ and $K_-\rightarrow -K_-$ in the definitions of F_{in} and F_{out}. In general, $F_{in}\neq\tilde{F}_{in}$ and $F_{out}\neq\tilde{F}_{out}$ (except in the limits of linear magneto-optical coupling only or quadratic magneto-optical

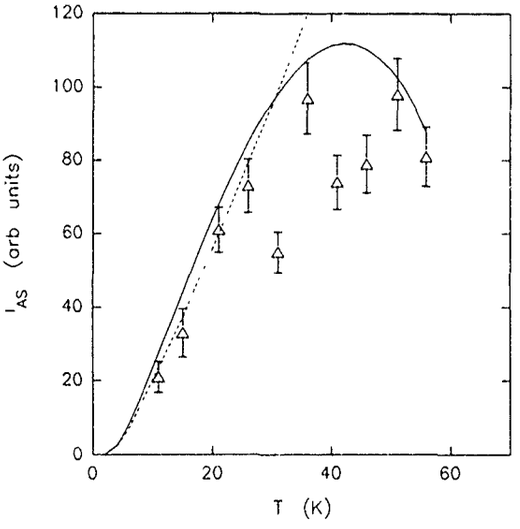

FIG. 4. Experiment and theory for the temperature dependence of the integrated intensity for anti-Stokes scattering. The experimental points (△) refer to (ZX) polarization. The theory curves are for $G_+/K_+=0$ (broken line) and $G_+/K_+=0.08$ (solid line).

coupling only), and consequently the intensity ratio I_{AS}/I_S differs from the usual thermal factor $n_M/(n_M+1)$ when both types of magneto-optical couplings apply. Also the individual temperature dependences of I_S and I_{AS} are modified and depend on the polarization, e.g., as confirmed experimentally for FeF_2 (see Ref. 5).

In making preliminary comparisons of theory with experiment for the Raman integrated intensities in MnF_2, we have assumed for simplicity that in-phase scattering is dominant. This would be expected because the deviation from tetragonal symmetry at a Mn^{2+} site is relatively small. For the Stokes data in Fig. 3, the theory predicts that $I_S(XZ)=I_S(YZ)$ at any given temperature, whatever the values are for K_+ and G_+, whereas $I_S(ZX)$ will be different (unless $G_+/K_+=0$). It is seen that the intensity data points (allowing for an experimental uncertainty of 10% to 20% typically) broadly confirm this prediction and allow us to make a rough estimate for the ratio G_+/K_+. First, we note that in the absence of any quadratic coupling ($G_+/K_+=0$), the intensities for all three polarizations would be described by the broken curve in Fig. 3, which provides an inadequate fit to the data. A much better fit is provided if G_+/K_+ is small and positive, as illustrated by the solid lines for $G_+/K_+=0.08$ in Fig. 3, where the upper line refers to (XZ) and (YZ) polarizations and the lower line to (ZX) polarization.

Similarly, for the anti-Stokes data, the role of quadratic coupling is to enhance the intensities in certain polarizations (making it easier to study experimentally) and to modify the temperature dependence. In Fig. 4 it can be seen that the variation of $I_{AS}(ZX)$ is much better described by the solid theory curve for $G_+/K_+=0.08$ than by the broken curve for $G_+/K_+=0$. Further evidence that $G_+/K_+\neq 0$ is provided by the intensity ratio I_{AS}/I_S in (ZX) polarization, where we have measurements at three different temperatures. Overall, from the T dependences of I_S and I_{AS} and from the behavior of I_{AS}/I_S, we deduce that G_+/K_+ lies approximately in the range 0.05 to 0.1.

In conclusion, we have presented new experimental data for the Stokes and anti-Stokes light scattering in MnF_2. From a preliminary analysis for the dependence of the integrated intensities on temperature and polarization, we obtain good agreement between theory and experiment. The results indicate that, while the linear magneto-optical coupling coefficient K_+ for in-phase scattering is dominant, there is an important contribution due to the quadratic in-phase coefficient G_+. A more detailed comparison between theory and experiment will be undertaken to determine if out-of-phase scattering is significant.

Controlling high frequency chaos in circular YIG films

D. W. Peterman, M. Ye, and P. E. Wigen
Department of Physics, The Ohio State University, Columbus, Ohio 43210

High power ferromagnetic resonance experiments involving thin circular YIG films produce chaotic oscillations with broad band frequency spectra in the 0.5–25 MHz range. To eliminate chaotic oscillations, a delayed feedback of the ac component of the ferromagnetic resonance signal was used to modulate one of the system parameters, the applied static magnetic field. The chaotic oscillations were converted to oscillations of reduced periodicity, and ultimately the quiescent state, as the gain in the feedback loop was increased. Similar results have been obtained in numerical simulations.

I. INTRODUCTION

The ability to control chaos has generated much experimental and theoretical interest.[1–6] Chaos in nonlinear dynamic systems can be controlled by applying small perturbations to an accessible system parameter to stabilize an unstable periodic orbit of the system's chaotic attractor. Using the method proposed by Ott, Grebogi, and Yorke (OGY),[1] the discrete perturbations to the chaotic system are calculated from the dynamic properties of the chaotic system near the unstable fixed point on the Poincare map corresponding to the periodic orbit onto which the system is going to be stabilized. This method of controlling chaos has been used successfully in a number of different experimental systems.[2–4]

In high power ferromagnetic resonance (FMR) experiments involving thin films, interactions between magnetostatic modes give rise to the observed nonlinear effects.[7,8] Above some threshold of the rf pumping power, instability oscillations in the absorption signal are observed. With increasing pumping power, the oscillations bifurcate from periodic to chaotic oscillations through period doubling.[9,10] The fundamental frequencies of chaotic oscillations in the absorption signals are typically in the range of 0.5–4.0 MHz. The high frequency dynamics in the FMR experiments make it difficult to control the chaos using discrete perturbations such as the OGY method. Consequently, for controlling chaos at high frequencies, a time delayed feedback method has been developed, in which the chaotic signal detected from the sample was time delayed and amplified before it was used to perturb a system parameter, the bias magnetic field of the sample. An advantage of this analog continuous feedback method is that no detailed calculation is necessary, allowing unstable orbits with submicrosecond periods to be controlled. In addition to stabilizing unstable periodic orbits of the attractor, the total suppression of auto-oscillations, the quiescent state, can be obtained by using this method as well. Suppression of chaos, resulting in periodic oscillations in experimental FMR using external sinusoidal modulation of the applied field has been previously reported.[11,12]

II. EXPERIMENT

The experiments were performed on circular disks of yttrium iron garnet (YIG) film roughly 2 mm in diameter and about 1 μm thick. A static magnetic field of about 2000 Oe was applied perpendicular to the film plane. The sample was excited into resonance by an rf pumping field of around 1.2 GHz which was produced by a slotline structure and oriented perpendicular to the static field.[13] Radio frequency absorption of the sample was detected by a diode. Under high rf pumping power, the absorption signals of the sample were observed to show periodic or chaotic oscillations with typical frequencies of a few MHz. The emergence of the oscillations is a function of the frequency and power of the rf pumping field, and the magnitude of the static bias field.[7,8]

In the experiments, the static field and rf power were chosen to produce a chaotic absorption signal from the sample. The ac component of the oscillating signal at the diode was fed into a delay line and then to a voltage to current converter amplifier. The current from the amplifier was used to drive a 20 turn coil 5 mm in diameter, approximately 1 mm above the YIG sample. The coil plane was adjusted to be parallel to the sample plane. The magnetic field produced by the coil perturbed the static magnetic field. The delay time and the gain of the feedback loop could be adjusted to achieve the control of chaos. Only the ac component in the output current from the amplifier was used for the perturbations. This was done to prevent a dc component that could bias the system out of the chaotic state by the application of a constant term to the bias field. This also allowed the perturbation to the system to approach zero as the oscillation amplitude in the rf absorption signal was reduced due to the effect of the perturbations.

Figure 1 shows an experimental result of controlling chaos. In this case the chaotic absorption signal of the sample was time delayed by 470 ns. As the feedback gain was increased, the absorption signal from the sample was converted to a period-4 oscillation by the perturbation fields of the coil. Further increase of the feedback gain resulted in a period-2, period-1, and finally the quiescent state, where only dc absorption was present in the FMR signal even though the pumping field was sufficient to maintain a chaotic state without the control. Delay coordinate plots of the data presented in Fig. 1 were used to construct attractors for the controlled and uncontrolled signals. From visual inspection of these attractors in delay coordinate space, it is apparent that the stabilized period-4 and period-2 orbits are unstable orbits of the unperturbed chaotic attractor. In the quiescent state, the amplitudes of the frequency components in the Fourier spectrum were found to be 20–30 dB less than those of the chaotic spectrum. A chaotic signal reemerged from the quiescent state when the gain was increased even further. Other samples show similar behavior.

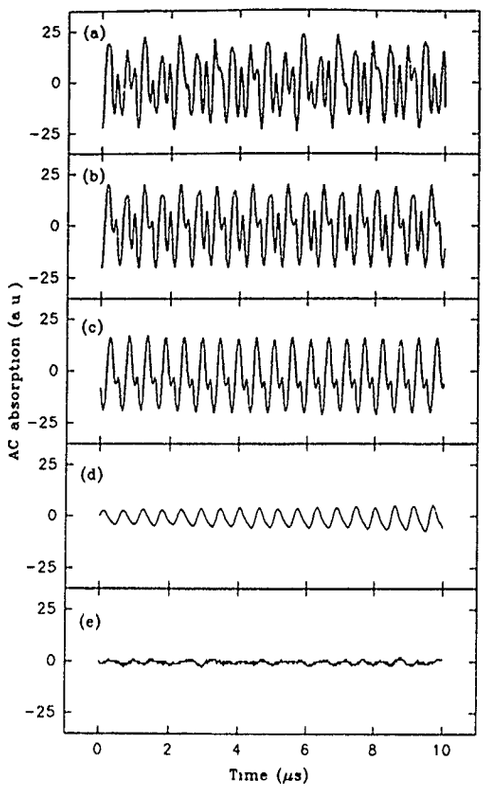

FIG. 1. Experimental results for controlling chaos in FMR using the time delayed feedback method. (a) Chaotic oscillation of FMR signal without perturbation. (b) Controlled period-4 oscillation (gain=0.45 arbitrary units). (c) Controlled period-2 oscillation (gain=0.80 a.u.). (d) Controlled period-1 oscillation (gain=5.50 a.u.). (e) The quiescent state (gain=6.50 a.u.), in which all oscillations were extinguished.

The amplitudes of the perturbation field required to maintain the periodic oscillations were in the range of 0.01–0.1 Oe. In preserving the quiescent state, the coil produced fields of less than 0.01 Oe. Thus, the ratio of perturbation field to the static magnetic field was about 10^{-4} for controlling periodic oscillations. The ratio was less than 10^{-5} for maintaining the quiescent state. Removal of the perturbation field caused the system to revert back to the chaotic state. It was possible to stabilize periodic orbits for several values of the feedback gain, but quiescence was only achievable with a delay time of around 470 ns.

Figure 2 shows another example of controlling chaos using time delayed feedback. However, in this example, the derivative of the sample absorption signal was time delayed before it was used to perturb the static field. Although the quiescent state has not yet been achieved, this example also shows a debifurcation route with increasing feedback gain, as seen in Fig. 1. With increasing rf power, the sample displayed a period doubling route to chaos. Applying time delayed feedback led to the stabilization of period-2 and period-1 orbits as the feedback gain was increased. In this example, the perturbation fields ranged from 0.1 to 0.5 Oe and the delay time used was 390 ns. In addition, the system attractors of both the controlled and uncontrolled signals in a delayed coordinate plot indicate that the controlled orbits were unstable orbits of the unperturbed chaotic attractor.

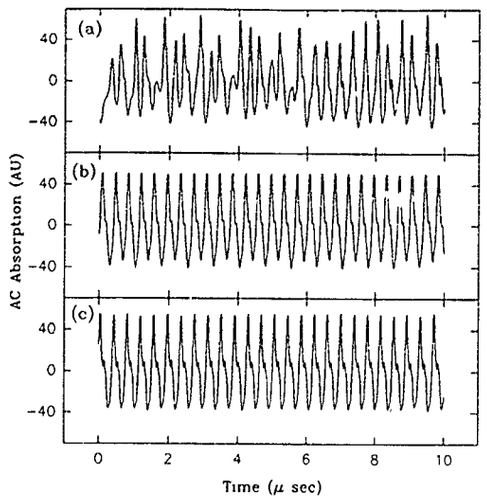

FIG. 2. Experimental results for controlling chaos in FMR using time delayed derivative feedback method. (a) Chaotic oscillation of FMR signal without perturbation. (b) Controlled period-2 oscillation (gain=2.4 a.u.). (c) Controlled period-1 oscillation (gain=4.2 a.u.).

III. SIMULATION

In the numerical simulations for controlling chaos in FMR using the time-delayed feedback method, the theoretical model developed by McMichael and Wigen was used.[8] The normal modes in thin circular YIG films are the magnetostatic modes, which have the form of Bessel functions. By integrating the equations of motion for the complex amplitude of these modes, the dynamic behavior of the system could be simulated. The FMR signal in the model, $S(t)$ was proportional to the sum of the imaginary parts of the mode amplitudes. This corresponded to the absorption signals measured in experiments. To simulate the time delay feedback, the static magnetic field H_0 in the equations of motion was modulated by the ac component of the FMR signal

$$H_{\text{total}}(t)=H_0+K[S(t-\delta)-\overline{S(t-\delta)}].$$

Here δ is the delay time and K is proportional to the gain of the feedback loop in the experiment. The dc component of the FMR signal $\overline{S(t-\delta)}$ is subtracted so that only the ac component in $S(t)$ is used for perturbation. The debifurcation route caused by increasing the feedback gain observed in the experiments is predicted in the simulations for both direct and derivative time delayed feedback. Also, the values and sensitivity of the delay times used in the model are similar to those observed in the experiment.

IV. CONCLUSION

In conclusion, through use of time delayed feedback, very high frequency chaotic absorption signals of FMR have been controlled by perturbing the static magnetic field continuously. In using this time delayed feedback method for controlling chaos, no detailed analysis of the system's attractor needs to be made. It is suitable for controlling the chaos in complicated systems which show high frequency oscillations. All that is required is the alteration of some system parameter by a time delayed signal of the system's output.

Another advantage of this method is that the chaotic state can be converted to the periodic state as well as the quiescent state. Finally, a mixture of the derivative signal and the original signal of the system's output can be used in this time delayed feedback method to control the chaos. Experiments using these techniques have shown promise and the work is ongoing.

Study of spin wave resonance in a superconductor with paramagnetic impurities

I. A. Garifullin, Yu. V. Goryunov, and G. G. Khaliullin
Kazan Physical-Technical Institute, Kazan 420029, Russia

The spin dynamics of paramagnetic impurities in a superconductor in the presence of external magnetic field has been studied both theoretically and experimentally. Long-wave excitations ($q \leqslant \xi^{-1}$, where ξ is the coherence length) are shown to have coherent spin-wave nature even in a paramagnetic phase. This effect is caused by the long-range ($R \sim \xi$) indirect exchange interaction between localized spins in a superconductor. The spin-wave effects in EPR of Er^{3+} ions in the superconducting (SC) $La_{1-x}Er_x$ thin films have been observed. An additional absorption at the high field side of the main resonance line which leads to its distortion has been found. Satisfactory description of all features of observed spectra was obtained by simulating the spectra with account for the microwave absorption by spin-wave excitations. The spin stiffness coefficient and the temperature dependence of the spin susceptibility of the SC lanthanum has been determined.

I. INTRODUCTION

Previous study of EPR of Er^{3+} ions in the superconductor[1] revealed anomalous behavior of the EPR linewidth ΔH which contrasted strongly with the expected change in ΔH. Instead of increasing due to the coherence effects the EPR linewidth narrowed sharply at the transition to the SC state. This effect was attributed to a new long-range exchange coupling of local moments in the SC phase due to correlations in Cooper condensate. This idea on additional indirect interaction was previously proposed by Anderson and Suhl[2] when they discussed the magnetic ordering in the SC phase.

The exchange-coupling integral in a superconductor[3] can be represented approximately as a sum of two parts $J_n(R)+J_s(R)$, the first one, acting at short distances,

$$J_n(R) \approx (J_0 v_0/4\pi R^3)\cos(2k_F R), \tag{1}$$

being the conventional *RKKY* interaction, and the second one

$$J_s(R) \approx (J_0 v_0/4\pi\xi^2 R)\,\delta\chi(T)\exp(-R/\xi), \tag{2}$$

being the SC correction. In Eqs. (1) and (2) v_0 is the volume per lattice site, and k_F is the Fermi momentum. The quantity

$$\delta\chi(T) = (\chi_p - \chi_s)/\chi_p \leqslant 1 \tag{3}$$

characterizes the decrease in the spin susceptibility χ_s of conduction electrons in the singlet BCS state as compared with the Pauli susceptibility χ_p. The constant $J_0 = J_{sf}^2 \rho(\epsilon_F) v_0/2$ is determined by the $s-f$ coupling constant J_{sf} and the electron density of states $\rho(\epsilon_F)$.

The additional interaction (2) is of an antiferromagnetic character. Its contribution to the total molecular field is of the same order of magnitude as the normal RKKY contribution (1). Furthermore, even when the concentration x of magnetic impurities is low, the number of spins $N \approx x\xi^3/v_0$ in the interaction region is anomalously high, since ξ is much larger than the lattice constant a. This introduces a new feature into spin dynamics: the long-wave excitations in an external magnetic field exhibit spin-wave behavior.

This report is devoted to the investigations of the spin-wave excitations of paramagnetic impurities in a superconductor in an external field.

II. THEORY

We calculated the dynamic susceptibility $\chi_{\omega,q}$ of local moments using the method of nonequilibrium statistical operator.[4] We obtained the following spin excitation spectrum at $q \leqslant \xi^{-1}$

$$\omega_q = \epsilon_q - i(\gamma_q^{ex} + \gamma_q^{dd}). \tag{4}$$

Here the spin excitation energy ϵ_q and its damping due to the exchange fluctuations (γ_q^{ex}) and dipole-dipole coupling (γ_q^{dd}) can be written as

$$\epsilon_q = g\beta H_0 - D'' q^2, \quad D'' \approx x\langle S^x\rangle \delta_\chi J_0 \xi^2, \tag{5}$$

$$\gamma_q^{ex} = D' q^2, \quad D' \approx x^{1/3}\langle S^x S^x\rangle^{1/2} J_0 a^2/4, \tag{6}$$

$$\gamma_q^{dd} = \frac{3}{5}(2\pi)^{5/2}\frac{x\langle S^x S^x\rangle^{1/2}}{J_0}\left(\frac{g^2\beta^2}{v_0}\right)^2. \tag{7}$$

$\langle S^x\rangle$ in Eq. (5) is the local moment polarization induced by magnetic field H_0, g being g value. Note that the q-dependent part of Eq. (5) is mainly contributed by the SC correction (2). It is precisely the long-range potential (2) which produces the transverse stiffness and real dispersion of spin excitations. Comparing the the energy (5) and the damping (6) we find that the condition for the existence of coherent spin motion

$$\frac{D''}{D'} \approx \left(\frac{\xi}{r_{av}}\right)\frac{g\beta H_0}{k_B T} \gg 1 \tag{8}$$

is easily satisfied in superconductors with the large coherence length ξ (compared with the average distance between impurities r_{av}) in magnetic fields of the order of several kilogauss and at liquid-helium temperatures. For $q > \xi^{-1}$ spin excitations are incoherent. The negative sign in the dispersion relation (5) reflects the antiferromagnetic nature of the potential (2); as the temperature decreases, the spectrum ϵ_q softens and magnetic order appears at nonzero wave vectors $q \sim \xi^{-1}$, as predicted by Anderson and Suhl.[2] For small q the damping is determined by the dipole contribution γ_q^{dd}. A "window" for spin-wave excitations exists if

$$x\langle S^x\rangle(\delta_\chi) J_0 > \gamma_q^{dd}. \tag{9}$$

 0021-8979/94/76(10)/6889/3/$6.00 © 1994 Amer.can Institute of Physics

This condition can also be satisfied, since exchange coupling in metals is usually stronger than the dipole-dipole interaction. Thus when the conditions (8) and (9) are satisfied, the long-wave spin dynamics has a magnon character. Of course, the contribution of these excitations to the thermodynamic parameters is negligible; the main fraction of the spectral density of spin fluctuations is incoherent and is determined by the short-range RKKY potential. Spin waves can only appear in the long-wave magnetic response of a superconductor.

We present below the experimental evidence for spin-wave effects in a superconductor with magnetic impurities, obtained in EPR studies performed in $La_{1-x}Er_x$ thin films.

III. EXPERIMENT

Films of $La_{1-x}Er_x$ with $x=0.008-0.02$ and thickness $L=2500-5000$ Å were prepared by separate thermal evaporation of the components from tantalum crucibles. The prepared film was coated immediately by a protective silicon monooxide layer of 3000 Å thickness.

X-ray structural analysis showed that all prepared films have mainly an face-centered-cubic structure. Measurements of the electrical resistivity, of the SC critical parameters, and of the magnetization in the SC state have been performed in addition to the EPR measurements. These data will be used in the discussion of our EPR results.

EPR experiments were carried out at 9.4 GHz in a rectangular TE_{102} cavity in the temperature range from 1.5 to 20 K. The out-of-plane angular dependencies of the spectra were observed with the microwave field lying in the film plane.

In the normal state we observed EPR line of Er ions which was just similar to that previously observed in bulk samples.[1] A change in the angle between the plane of the sample and the direction of the dc magnetic field had no effect on the position and shape of the EPR line [Fig. 1(a)]. Upon transition to the SC state in perpendicular orientation of the film to the direction of dc magnetic field the line shape did not change [Fig. 1(d)]. In a longitudinal magnetic field, however, the shape of the signal became drastically distorted as the temperature was lowered [see Figs. 1(b) and 1(c)]. The degree of distortion of the high field wing of absorption signal was dependent on thickness of film and erbium concentration in the sample (Fig. 2). These effects are illustrated by the EPR spectra shown in Figs. 1 and 2.

IV. ANALYSIS OF RESULTS

It is unlikely that the unusual behavior of the EPR spectrum in the studied films could be attributed to a magnetic field distribution in a vortex lattice which differs from that found in a bulk sample. The amplitude of the magnetic field variation and the value of the London penetration depth λ, which we estimated from our measurements of the critical field and the SC moment of the films, turned out to be on the order of 50 Oe and 600 Å, respectively. These values are essentially the same as those obtained for the bulk samples.[1]

We believe that the shape of the signal is distorted because of the additional absorption of the microwave energy

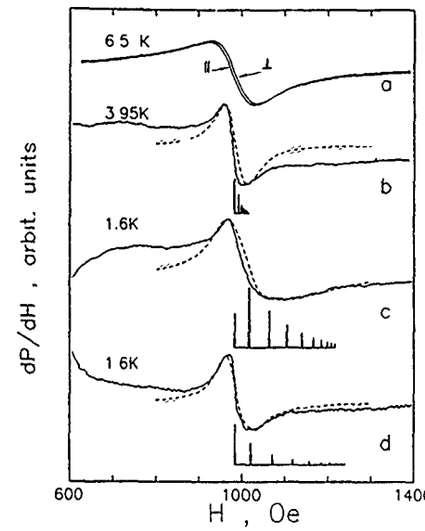

FIG. 1. EPR spectra for the sample with $L=4800$ Å, $x=0.014$ and critical temperature $T_c=5.0$ K at different temperatures: in a normal state with magnetic field oriented parallel and perpendicular to the plane of the film (a) and in the SC state with magnetic field oriented parallel (b) and (c) and perpendicular (d) to the plane of the film. The dashed lines are the computed spectra. The relative intensities and arrangement of the spin-wave resonance lines in the computed spectra are indicated below each spectrum.

by the nonuniform spin-wave excitations discussed above. The resonance field H_n for excitation of a magnon with momentum q_n can be approximately written as

$$H_n=H_0+H_0\frac{xJ_0\delta\chi(T)}{k_BT}\frac{S(S+1)}{3}\frac{(\xi q_n)^2}{1+(\xi q_n)^2}. \tag{10}$$

The intensity of the spin-wave satellites is determined by the boundary conditions at the surface of the film and the degree of nonuniformity of the microwave field $H_1(z)$. In the case of symmetric excitation

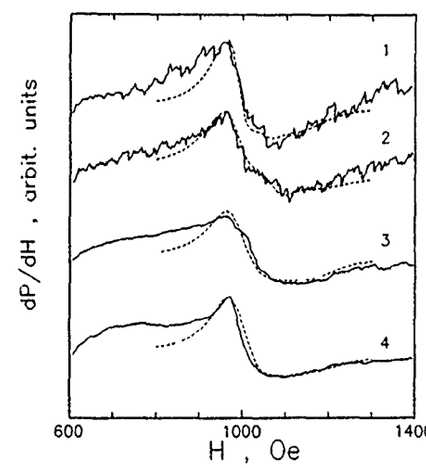

FIG. 2. EPR spectra for the samples No. 1 ($L=2500$ Å, $x=0.014$, and $T_c=5.0$ K)-1, No. 2 ($L=3380$ Å, $x=0.02$, and $T_c=4.8$ K)-2, No. 3 ($L=4030$ Å, $x=0.009$, and $T_c=5$ 2 K)-3, No. 4 ($L=4800$ Å, $x=0$ 014, and $T_c=5.0$ K)-4 at a temperature of 1.6 K with the magnetic field oriented parallel to the surface of the film. The dashed lines were computed.

$$H_1(z)=H_1\frac{ch(k_0z)}{ch(k_0L/2)},\quad k_0^2=i\frac{4\pi\omega}{c^2}\sigma(\omega), \tag{11}$$

where H_1 is the amplitude of the incident wave and $\sigma(\omega)$ is the complex conductivity at the resonance frequency. It is well known that in type-II superconductors with a vortex lattice the conductivity is anisotropic and depends strongly on the relative orientation of the dc magnetic field H and of the electric component E_1 of the microwave field in the sample.[5] It can be shown that the penetration depth of the microwave field is much smaller for parallel orientation of the film. Therefore, the distribution of microwave field in the SC state is most inhomogeneous in this geometry and in this case the best demonstration of spin-wave effects would be expected. To calculate the spectra it is necessary to know the parameters of the studied samples: the coherence length ξ and the inverse penetration depth k_0 of the microwave field. These values were estimated from our measurements of the critical field H_{c2}, of the diamagnetic susceptibility, and of the integral intensity of the EPR signal. The obtained values of $\xi(0)=200$ Å and $\lambda(0)=600$ Å give the possibility to fit all spectra as it is shown in Figs. 1 and 2. Some discrepancy between the calculated and experimental spectra at low field wing is caused by nonresonant absorption of microwave power by superconductor which has been observed earlier for bulk samples.[1] The only fitting parameter was

$$A=J_0S(S+1)\delta_\chi/3, \tag{12}$$

which entered in expression (10) and was fitted for each spectrum independently. The obtained temperature dependence of A value is shown in Fig. 3. This figure actually reflects the temperature behavior of $\delta_\chi(T)$. The solid curve corresponds to the temperature dependence of δ_χ in a BCS superconductor. By knowing A it is possible to determine the spin stiffness coefficient $D''=0.04$ cm^2/s at $T=1.6$ K and

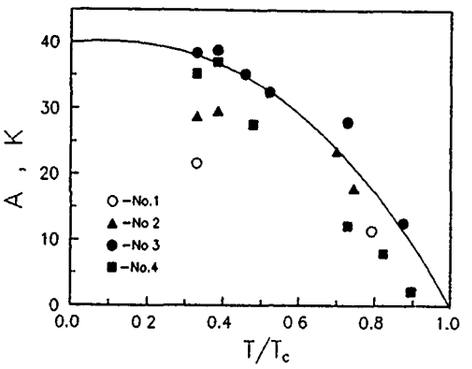

FIG. 3. The parameter A as a function of the reduced temperature for the samples No. 1–4. The solid line corresponds to $\delta_\chi(T)$ of a BCS superconductor.

$x=0.01$. Thus we have shown experimentally that in a superconductor in an external magnetic field weakly damped spin waves exist. These excitations resulted from the nonlocal nature of spin susceptibility of the superconductor. Their observation is the direct evidence of the existence of a long-range exchange interaction between impurities. Previously, spin waves in paramagnetic spin systems have been observed in two particular cases: first the spin waves in the Fermi liquid[6] and second the nuclear spin waves in magnetics.[7]

The two-magnon absorption of the electromagnetic waves in the exchange noncollinear magnetic phase of four-sublattice antiferromagnet Nd_2CuO_4 has been considered. The spin-wave density of states and the frequency dependencies of the absorption coefficient have been calculated. It is shown that the intensity of the two-magnon absorption by exchange magnons in exchange-noncollinear magnets is substantially larger than in magnets collinear in the exchange approximation.

I. INTRODUCTION

The two-magnon absorption (TMA) phenomenon consists in the decay of a quantum of the electromagnetic radiation into two magnons. The intensity of the TMA proportional to the density of magnon states. Thus, it will be higher for those regions of the spectrum which correspond to the flattened portions of the dispersion curves. In the case of the three-dimensional magnets the flattening of the dispersion curves takes place only for the exchange magnons due to the changes of the spectrum under the action of a constant external magnetic field.[1] The TMA has been investigated in two-sublattice quasi-two-dimensional antiferromagnets.[2–4] The TMA by the exchange magnons was studied for the first time in the three-dimensional antiferromagnet in Ref. 1 and then in the quasi-two-dimensional one in Ref. 5. The magnets collinear in the exchange approximation have been considered. In these magnets the TMA is due to the interaction of the magnetic component of the electromagnetic wave with the crystal. The TMA in exchange-noncollinear magnets has not been considered.

The exchange-noncollinear four-sublattice antiferromagnet Nd_2CuO_4 is unique from the point of view of the experiment: First, because its magnon spectrum has quasi-two-dimensional character for some particular directions of the wave vector;[6] second, due to the special magnetic and crystal symmetry of this compound the TMA is electro-dipole active in the exchange approximation.

II. SPIN-WAVE SPECTRUM OF Nd_2CuO_4

The detailed information about the crystal and magnetic symmetry and possible magnetic phases of Nd_2CuO_4 can be found in Ref. 7. The magnon spectrum in noncollinear phase has four branches, three of which are acoustic, while the fourth is the exchange spin wave.[6] In the case $\mathbf{k}\|[001]$ (the fourfold axis of the tetragonal crystal) the energies of the acoustic modes A_1 and A_2 are degenerate and do not depend on $\mathbf{k}$. This particular case of the pure two-dimensional behavior of the A_1 and A_2 branches is connected with the specific crystal and magnetic symmetry. As to the exchange E mode, it has a very weak dispersion and its dispersion relation has also a quasi-two-dimensional character.

In the case when $\mathbf{k}$ has components in the plane parallel to CuO_2 layers (the crystal planes normal to [001]) the magnon dispersion relations are typical for the three-dimensional magnet. As in all parent compounds of the high-temperature superconductors the intralayer exchange interaction is much greater than the others.

The parameters describing the copper magnetic subsystem of Nd_2CuO_4 may be roughly estimated on the basis of the results of Refs. 8–10 (see also Ref. 6). The frequencies of the homogeneous vibrations are as follows;[6,7] $\omega_{A_1,A_2} = 16S\sqrt{J|a_2|}$; $\omega_{A_3} = 16S\sqrt{J|a_2-a_4|}$ and $\omega_E = 16S\sqrt{JD}$, where J is approximately equal to intralayer exchange; a_i ($i=2, 4, 6, 8$) are the anisotropy constants (see Ref. 7 for details). The value of $J\approx 870$ cm^{-1} was obtained in Ref. 8 and it is supposedly the largest of the exchange parameters. Using experimental results[9,10] one can get $|a_2|\approx 2.87\times10^{-4}$ cm^{-1} and $|a_2-a_4|\approx 3.32\times10^{-5}$ cm^{-1}. The other anisotropy constants have to be of the same order of magnitude.[6,7] The values of the four-site D and of the interlayer I exchange interactions are unknown at present. The results of the estimations allow us to suppose that $J\gg D\gg A$, where A is the combinations of the anisotropy constants.

Numerical calculations will be done for the I and D values related to the known value of J with $I=10^{-1}J$, and $D=10^{-3}J$. The corresponding magnon spectrum can be found in Ref. 6.

III. TMA OF ELECTROMAGNETIC WAVES

The interaction Hamiltonian with a uniform external electromagnetic field is

$$H_{\text{int}} = \sqrt{N}[-g_{ij}\mu_B h_i F_j(0) + e_j P_j(0)], \tag{1}$$

where h_i and e_i are the components of the magnetic and electric vectors of the electromagnetic wave, $i, j = x,y,z$, the x, y and z axes, are oriented along the [100], [010], and [001] crystal axes, respectively; g_{ij} is the g-factor tensor; $F_i(0)$ and $P_i(0)$ are the zero Fourier components of the magnetization vector $\mathbf{F}=\sum_{\alpha=1}^{4}\mathbf{S}_\alpha$ (see Ref. 7 for details) and the

[a)]On leave from: Institute for Single Crystals, Academy of Sciences of Ukraine, Kharkov, 310001, Ukraine.

electric dipole moment associated with the pair of spins,[11] respectively. Magnetic symmetry allows the existence of the electric dipole moment, associated with the pair of spins, having an exchange nature

$$P_j(0)=\sum_{\alpha,\beta;\mathbf{k}} \pi^{j}_{\alpha\beta}(\mathbf{k})S_\alpha(-\mathbf{k})S_\beta(\mathbf{k}). \tag{2}$$

The tensors $\pi^{j}_{\alpha\beta}(0)$ are nonzero for those pairs of the Cu^{2+} ions that cannot be permuted by the inversion operation and also for the ions whose group of positional symmetry does not contain an inversion. That is why for the crystal symmetry under consideration the tensor $\pi^{j}_{\alpha\beta}(0)$ is equal to zero in case the lattice structural distortions are absent (see Ref. 7 for details). The other mechanisms that contribute to **P** are not considered here.

The part of the expression (1), which is quadratic with respect to the magnon creation and annihilation operators, may be obtained with the help of quantization of the spin-system Hamiltonian described in Ref. 6. We have

$$H^{(m,e)}_{\text{int}}=\sum_{\mathbf{k}} [\Phi^{(m,e)}_{A_1A_3}(\mathbf{k})\xi^{+}_{\mathbf{k}A_1}\xi^{+}_{-\mathbf{k}A_3} + \Phi^{(m,e)}_{A_2E}(\mathbf{k})\xi^{+}_{\mathbf{k}A_2}\xi^{+}_{-\mathbf{k}E}+\text{h.c.}], \tag{3}$$

where the amplitudes $\Phi^{(m,e)}_{\sigma,\nu}$ are calculated in the nearest-neighbor approximation; the superscripts m and e denote the magneto-dipole and electro-dipole channels of the TMA, respectively. Expression (3) corresponds to the case of h_x component of the magnetic vector or e_x component of the electric vector of electromagnetic wave. In the case of h_y or e_y one has to change $A_2 \Leftrightarrow A_1$ in (3). For the orientation of the magnetic component of the electromagnetic wave along the z axis the TMA will not take place in the approximation considered. The exchange magnon taking part in the absorption process is always accompanied by the acoustic spin wave. In contrast to the three-dimensional magnets[1] collinear in the exchange approximation the amplitudes $\Phi^{(m,e)}_{AE}$ do not contain any small parameter. The TMA leading to the generation of the magnons corresponding to the same branches of spectrum is absent.

The separation of the electro-dipole and magneto-dipole channels of the TMA may be carried out by the proper choice of the orientation of the polarizations of the electromagnetic-field components and the propagation direction of the incident radiation. For example, in the case when $\mathbf{k}\|0y$ and $\mathbf{e}\|0z$ only magneto-dipole absorption by the A_1, A_3 and E, A_2 magnons takes place. For the magneto-dipole absorption by the A_1 and A_3 branches in the frequency region $\omega \ll \epsilon_{ex}=8SJ$, one can obtain

$$K^{(h)}_{A_1,A_3}(\omega)\propto \frac{(g\mu_B)^2}{4\omega^2_{ex}\omega^2}\int_{t_0(\omega)}^{1}\frac{[\omega_4^2\ \text{sign}(a_4)+\omega_E^2(1-t)]^2}{\sqrt{1-t^2}}\,dt. \tag{4}$$

where (and henceforth) the notations $\omega_i = 16S\sqrt{J|a_i|}$ and $\omega_{ij} = 16S\sqrt{J|a_i-a_j|}$ $(i=2, 4, 6, 8)$ are used. The electro-dipole contribution to the TMA is as follows:

$$K^{(e)}_{A_1,A_3}(\omega)\propto \frac{(S\pi_{12})^2}{16\omega^2_{ex}\omega^2}\int_{t_0(\omega)}^{1}[\omega^2+\omega_4^2\ \text{sign}(a_4) + \omega_E^2(1-t)]^2 t(1-t^2)^{-1/2}\,dt. \tag{5}$$

The limiting value $t_0(\omega)$ in Eqs. (4) and (5) is determined by the relations

$$t_0(\omega)=\begin{cases}(\omega_E^2-\omega^2+\omega_4^2\ \text{sign}(a_4)+2\omega\omega_{A_1})\omega_E^{-2}, \\ \quad \text{at}\ \ \omega_0\leqslant\omega\leqslant\omega_1 \\ 0 \quad \text{at}\ \ \omega_1\leqslant\omega,\end{cases}$$

in which $\omega_0=\omega_{A_3}+\omega_{A_1}$ and $\omega_1=\omega_{A_1}+\sqrt{\omega_E^2+\omega_{A_3}^2}$. The coefficients of the magneto-dipole and electro-dipole absorption by the A_2 and E modes may be represented by the expressions

$$K^{(h)}_{A_2,E}(\omega)\propto \frac{(g\mu_B)^2}{4\omega^2_{ex}\omega^2}\int_0^{t_0(\omega)}\frac{[\omega_6^2\ \text{sign}(a_6)+\omega_E^2(1+t)]^2}{\sqrt{1-t^2}}\,dt \tag{6}$$

and

$$K^{(e)}_{A_2,E}(\omega)\propto \frac{(S\pi_{12})^2}{16\omega^2_{ex}\omega^2}\times\int_0^{t_0(\omega)}\frac{[\omega^2+\omega_6^2\ \text{sign}(a_6)+\omega_E^2(1+t)]^2 t}{\sqrt{1-t^2}}\,dt, \tag{7}$$

respectively. In these formulas

$$t_0(\omega)=\begin{cases}(\omega^2-\omega_6^2-\omega_E^2-2\omega\omega_{A_2})\omega_E^{-2} & \text{at}\ \ \omega_0\leqslant\omega\leqslant\omega_1, \\ 1 \quad \text{at}\ \ \omega_1\leqslant\omega,\end{cases}$$

and

$$\omega_0=\omega_{A_2}+\sqrt{\omega_E^2+\omega_{62}^2\ \text{sign}(a_6-a_2)},$$

$$\omega_1=\omega_{A_2}+\sqrt{2\omega_E^2+\omega_{62}^2\ \text{sign}(a_6-a_2)}.$$

Following from Eq. (4),(5), and (6),(7), $K^{(e)}_{\mu\nu}(\omega)$ increase with increasing frequency whereas the frequency dependence of $K^{(h)}_{\mu\nu}(\omega)$ is nonmonotonic. Such a behavior is connected with specific features of the spin-wave spectrum and the structure of $\Phi^{(m)}_{\mu\nu}(\mathbf{k})$. The quasi-two-dimensionality of the spin-wave spectrum leads to different behavior in the amplitudes of magnon normal modes in two regions of the wave vector **k** space. These amplitudes of magnon normal modes enter the expressions for $\Phi^{(m,e)}_{\mu\nu}(\mathbf{k})$. In the first region $(ka_0) \ll \sqrt{(D+A)J^{-1}}$ (a_0 is the lattice parameter in the basal plane) these amplitudes do not depend or depend weakly on the k_z component of the wave vector which varies from 0 to π/c_0. So, in this region of the wave vectors they are approximately equal to their values at $\mathbf{k}=0$. The second region is determined by $\sqrt{(D+A)J^{-1}} \ll (ka_0) \ll 1$. In this region $\Phi^{(m)}_{\mu\nu}(\mathbf{k})$ is proportional to the inverse square of the frequency. The frequency dependencies of the coefficients $K^{(h)}_{A_1,A_3}(\omega)$ and $K^{(e)}_{A_1,A_3}(\omega)$ are presented in Fig. 1. The curves are obtained by the numerical integrations of the correspondent expressions using the values of the parameters of the copper subsystem given in the previous section. The dependencies of the coefficients $K^{(h)}_{A_2,E}(\omega)$ and $K^{(e)}_{A_2,E}(\omega)$ are

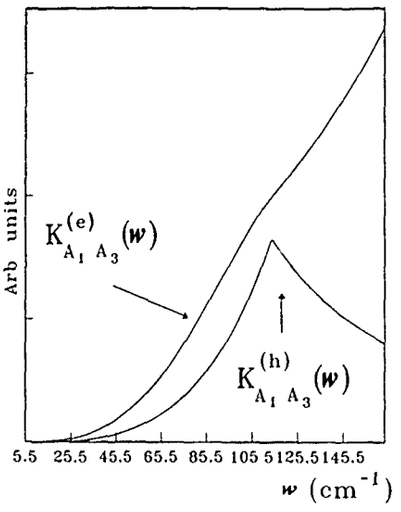

FIG. 1. The frequency dependencies of the absorption coefficients $K^{(h)}_{A_1,A_3}(\omega)$ and $K^{(e)}_{A_1,A_3}(\omega)$.

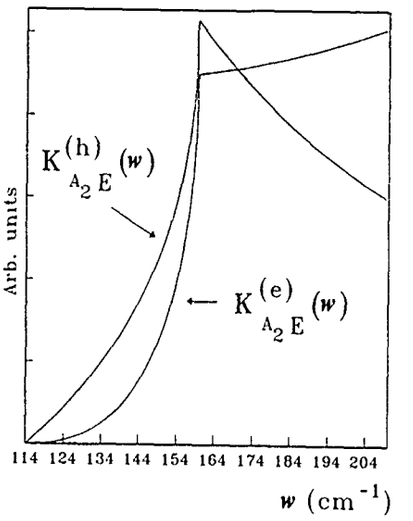

FIG. 2. The frequency dependencies of the absorption coefficients $K^{(h)}_{A_2,E}(\omega)$ and $K^{(e)}_{A_2,E}(\omega)$.

given in Fig. 2. The dependence of the coefficient of magneto-dipole absorption does not follow the frequency dependence of the density of magnon states in the low-frequency region. This discrepancy in the frequency dependencies of the absorption coefficient and the spin-wave states density is caused by the structure of the $\Phi^{(m)}_{\mu\nu}(\mathbf{k})$ amplitude discussed above.

The TMA by the exchange mode has the main peculiarities similar to that of the absorption by the acoustic magnons. They are the nonmonotonic behavior of $K^{(h)}_{A,E}(\omega)$ in the region of the frequencies near the activation energy of the exchange and acoustic magnon and monotonic behavior of $K^{(e)}_{A_2,E}(\omega)$ in the same region. It is important to note that the peak height of the magneto-dipole absorption by the exchange mode is of the same order of magnitude as the peak height of the magneto-dipole absorption by the acoustic modes. Thus, the TMA, by the exchange modes in exchange noncollinear magnets in the absence of the external magnetic field, has substantially larger intensity than in many-sublattice magnets collinear in exchange approximation. It is caused by the fact that at $\omega \ll \omega_{ex}$ the heights of the step of the density of magnon states for the exchange and acoustic modes coincide with each other.

It is necessary to note an interesting peculiarity of the TMA originated from the structure of the H_{int}. In the case when the radiation is propagated along the z axis the absorption coefficient does not depend on the orientation of the polarization of the incident electromagnetic wave with respect to the x and y axes. It is connected with the fulfillment of the relations.

$$\omega_{A_1}(k_x,k_y,k_z)=\omega_{A_2}(k_y,k_x,k_z),$$
$$\omega_{A_3}(k_x,k_y,k_z)=\omega_{A_3}(k_y,k_x,k_z). \tag{8}$$

From relation (8) and explicit form of $\Phi_{\mu\nu}(\mathbf{k})$ it follows that

$$K^{(h_x)}_{A_1,A_2}(\omega)=K^{(h_y)}_{A_2,A_3}(\omega), \quad K^{(e_x)}_{A_1,A_3}(\omega)=K^{(e_y)}_{A_2,A_3}(\omega). \tag{9}$$

During the experimental investigations of the TMA with the scheme of the experimental setup using the fixed frequency of the generator the absorption channels A_1,A_3 and A_2,A_3 will be undistinguishable with respect to the energy. Thus, for the case $\mathbf{k}\|0z$ and arbitrary polarization $h_x=h\cos\varphi$, $h_y=h\sin\varphi$ the combined absorption coefficient observed in the experiments does not depend on φ. The combined absorption coefficient

$$K(\omega)=K^{(h)}_{A_1,A_3}(\omega)+K^{(e)}_{A_1,A_3}(\omega)$$

contains the contributions which are determined by formulas (5) and (6). The same phenomenon takes place for the case of the absorption by the exchange mode E because relations (8) and (9) are valid at the interchange $A_3 \Rightarrow E$.

Surface precession solitons (surface "Magnetic drops") in uniaxial magnetics (abstract)

Yurij Bespyatykh, Igor Dikshtein, and Sergey Nikitov
Institute of Radioengineering & Electronics of the Russian Academy of Sciences, Moscow, Russia 103907

Surface spin waves, localizing near the surface of magnets as a consequence of nonlinear properties of material, have been studied in Ref. 1. According to the Lighthill criterion this wave is modulationally unstable. This can lead to the creation of nonunidimensional surface states. In this work, a new class of nonlinear exitations in a pure exchange-coupled uniaxial ferro- and antiferromagnets is considered. These exitations are 3D surface precession solitons or "magnetic drops" localized near the surface of a crystal. Such solitons are the space localized solutions of the Landau–Lifshits equation of motion for magnetization field with appropriate boundary conditions for the spins on the surface of magnetics. They keep their dynamic structure during the motion in space. The conditions of their stability are found. The problem of soliton motion is considered. It is shown that energy and precession frequency for surface 3D solitons is less than for volume 3D solitons, which was studied in Ref. 2. The possibility of experimental registration of such solitons is discussed.

Nonlinear self-localized surface spin waves in ferromagnets (abstract)

Alan Boardman
Salford University, Salford M54WT, United Kingdom

Yurij Bespyatykh, Igor Dikshtein, and Sergey Nikitov
Institute of Radio Engineering and Electronics of the Russian Academy of Sciences, Moscow 103907, Russia

It is well known that in linear theory, surface spin waves (SW) do not exist in a pure exchange-coupled ferromagnet for the case of free spins at the surface. However, in these approximations of the linear theory the plane volume spin waves (VW), propagating along the surface of a ferromagnet, satisfies not only the Landau–Lifshitz equation for the magnetization motion, but the boundary conditions for the free surface spins. Such VW can be unstable and can be transformed into SW under small changes of a magnetic medium, e.g., if the surface spins are partly pinned. In the present work a new type of self-localized SW in the ferromagnet has been considered. The existence of such waves is conditioned entirely by the nonlinear properties of a ferromagnet. The penetration length of such SW is proportional to 1/A, where A is a maximum of the magnetization amplitude on the surface of the crystal. The dispersion equations have been obtained for pure exchange and dipole-exchange nonlinear SW. In the latter case the influence of the second harmonic generation on the wave propagation at the fundamental frequency was studied. The conditions when the SW excites the VW, carrying the energy into the volume of the crystal, are derived. The nonlinear Schrödinger equation for the SW envelope amplitude was derived and its solitonic solutions are obtained. The estimations of threshold values for the wave numbers of the propagating waves are provided.

Spin wave dispersion in ferromagnetic nickel (abstract)

J. M. Rejcek, J. L. Fry, and N. G. Fazleev[a)]
Department of Physics, University of Texas at Arlington, Arlington, Texas 76019-0059

The spin wave dispersion in ferromagnetic nickel has been computed in random phase approximation using the wave vector and frequency dependent magnetic susceptibility including many body enhancement effects. The latter were included using an orbital basis to invert the susceptibility matrices that are encountered in a local density, first principles version of a Stoner-like theory of many body enhancements. The complicated computer codes employed in the calculation were tested by computing numerically the wave vector and frequency dependent spin and orbital magnetic susceptibility of the uniform electron gas and comparing with known analytic expressions. Numerical work was done using the analytic tetrahedron method. For nickel the theory was simplified by introducing a single adjustable parameter in lieu of calculation of complicated integrals involving the band structure. The parameter was adjusted to yield agreement with a long wavelength spin wave neutron scattering measurement. With the fit parameter, good agreement with the experimental dispersion of spin waves in nickel was obtained for other wavelengths as well.

Ferromagnetic resonance and Brillouin light scattering from epitaxial Fe_xSi_{1-x} films on Si(111) (abstract)

M.. Mendik,[a] Z. Frait,[b] H. von Känel, and N. Onda
Laboratorium für Festkörperphysik, ETH, 8093 Zürich, Switzerland

The magnetic properties of epitaxial Fe_xSi_{1-x} films on Si(111) have been determined by means of ferromagnetic resonance (FMR) and Brillouin light scattering (BLS). The investigated films are (111) oriented, with thicknesses $h=150$ Å, 250 Å, 710 Å, and Fe concentrations $x=0.75$, 0.79, and 0.75, respectively.[1] All experiments have been carried out at room temperature. For BLS, the frequencies of both surface and bulk magnons have been measured as a function of the external in plane field **H** and the in plane direction of magnon propagation versus the main crystallographic axis. Moreover, the wave vector dependence has been used to identify the surface and bulk magnons present in the thicker films. FMR has been used in the parallel configuration (PC) and normal configuration (NC), where the external applied field lies in the sample plane and normal to the sample, respectively. Several waveguide setups were used to cover the frequency range from 18 to 92 GHz. For the numerical analysis we used the resonance conditions for a thin single crystalline film grown in the (111) plane. From our fits we obtained for the Landé g value 2.1, for the saturation induction $4\pi M_s=8.8$ kG, 10.7 kG, 13.7 kG for $h=150$ Å, 710 Å, and 250 Å, respectively. The magnetic parameters have been found to depend strongly on the Fe concentrations and Fe_xSi_{1-x}-Si substrate interface interdiffusion. The magnetic parameters of epitaxial Fe_xSi_{1-x} films are in agreement with the data obtained from single crystals by Hines *et al.*[2] The Landau–Lifshitz FMR relaxation constant is very small, ranging from 5 to 8×10^7 rad/s.

Nuclear secondary echo in ferromagnets caused by quadrupole and Suhl–Nakamura interactions

V. I. Tsifrinovich
Physics Department, Polytechnic University, Six Metrotech Center, Brooklyn, New York 11201 and Bramson ORT Technical Institute, 321 Avenue N, Brooklyn, New York 11230

The formation of the secondary nuclear spin echo signals in ferromagnets has been investigated taking into consideration the quadrupole and Suhl–Nakamura interactions. It is assumed that the inhomogeneous distribution of the quadrupole frequency $\omega_Q+\delta\omega_Q$ is independent of the distribution of nuclear magnetic resonance frequency $\omega_n+\delta\omega_n$, and a characteristic size of these inhomogeneities is small in comparison to the correlation radius of the exchange interaction in the electron ferromagnetic system. It is shown that the quadrupole interaction causes the formation of the secondary echo signals at $t=(2k+1)\tau$, $1\leqslant k\leqslant I-1/2$, where I is the nuclear spin, the time t is measured from the second rf pulse, and τ is the time interval between the rf pulses. The spectrum of the spin echo signal with maximum at $t=t_E$ contains $(2I+1-t_E/\tau)$ frequencies. The Suhl–Nakamura interaction causes the additional echo signals with maximum at even values t/τ.

INTRODUCTION

It is well known that in ferromagnets after the action of two pulses with the nuclear magnetic resonance (NMR) frequency one can observe not only the usual Hahn's nuclear spin echo but also the secondary echo signals.[1] This article is dealing with the investigation of these signals.

First of all we note that the secondary echoes may be caused by two "external" circumstances. (1) High frequency of the pulse pairs repetition in the real experiments. If the period of repetition is small in comparison with the time of longitudinal relaxation, then the secondary echoes may be caused by the influence of previous pairs. (2) If the connection between the magnetic system of a sample and a measuring circuit is strong enough, the currents in the circuit, that are induced by the first echo signal, act on a sample and cause the additional echo signal, etc. Furthermore, we will suggest that these situations are eliminated, so we will consider internal mechanisms of a secondary echo formation.

QUADRUPOLE INTERACTION

The Hamiltonian of a nuclear system with the quadrupole interaction is

$$H=-\hbar\{(\omega_n+\delta\omega_n)I_z+(1/2)(\omega_Q+\delta\omega_Q)I_z^2+(1/2)\times[q_1(t)+q_2(t)][I_+\exp(i\omega t)+\text{C.C.}]\},\quad(1)$$

where I is the nuclear spin, $\omega_n+\delta\omega_n$ is the inhomogeneous NMR frequency, $\omega_Q+\delta\omega_Q$ is the inhomogeneous quadrupole frequency, and $q_p(t)$ is the envelope of the pth rf pulse. The evolution of nuclear spins is described by the equation of motion for the density matrix ρ

$$i\hbar\dot{\rho}=[H,\rho].\quad(2)$$

To describe the echo signals we calculated the average transverse component of a nuclear spin

$$\langle I_+\rangle=\int_{-\infty}^{\infty}\int g(\delta\omega_n,\delta\omega_Q)\mathrm{Tr}(I_+\rho)d(\delta\omega_n)d(\delta\omega_Q),\quad(3)$$

where $g(\delta\omega_n,\delta\omega_Q)$ is a distribution function.

The secondary echo formation depends on values $\langle|\delta\omega_n|\rangle\tau$ and $\langle|\delta\omega_Q|\rangle\tau$, where τ is the time interval between the rf pulses, $\langle|\delta\omega_n|\rangle$ and $\langle|\delta\omega_Q|\rangle$ are characteristic inhomogeneities of NMR and quadrupole frequencies. The situation $\delta\omega_n=0$ that is typical for nonmagnetic substances was first considered by Solomon.[2] The opposite situation $\delta\omega_Q=0$ was considered by Abe *et al.*[1]

We have considered another realistic situation

$$\langle|\delta\omega_n|\rangle\tau,\langle|\delta\omega_Q|\rangle\tau\gg 1.\quad(4)$$

In this case the nuclear spin system acquires an inhomogeneous phase caused by the inhomogeneity in both $\delta\omega_n$ and $\delta\omega_Q$. For the signal formation this inhomogeneous phase must be canceled after the second rf pulse. For analytical calculations we used the Symbolic Formulas method.[3] The results of calculations depend sufficiently on correlation between inhomogeneities of $\delta\omega_n$ and $\delta\omega_Q$. We have considered the situation when inhomogeneities of $\delta\omega_n$ and $\delta\omega_Q$ were independent. According to our calculations the echo signals appear at

$$t=(2k+1)\tau,\quad 0\leqslant k\leqslant I-1/2,\quad(5)$$

where t is measured from the end of the second pulse. (The usual Hahn's signal corresponds to the value $k=0$).

If $\omega_Q>\langle|\delta\omega_Q|\rangle$, i.e., the NMR spectrum is a quadrupole split one, then the spectra of echo signals are essentially different. The spectrum of the spin echo with maximum at $t=t_E$ contains $(2I+1-t_E/\tau)$ frequencies. The echo spectrum at $t=\tau$ has $2I$ frequencies that coincide with the quadrupole split NMR spectrum, the echo spectrum at $t=3\tau$ has

 0021-8979/94/76(10)/6898/2/$6 00 © 1994 American Institute of Physics

$(2I-2)$ frequencies and so on. For half-integer spin I the spectrum of the echo at $t=t_E$ consists of frequencies ω

$$\omega=\omega_n\pm q\omega_Q, \quad 0\leqslant q\leqslant I-t_E/2\tau. \tag{6}$$

For integer spin I we have received

$$\omega=\omega_n\pm\omega_Q(q+1/2), \quad 0\leqslant q\leqslant I-1/2-t_E/2\tau. \tag{7}$$

In particular for $I=3/2$ the spectrum of the echo at $t=\tau$ contains frequencies $\omega=\omega_n,\omega_n\pm\omega_Q$, and the spectrum of the echo at $t=3\tau$ has only one frequency $\omega=\omega_n$. This result is in agreement with experiments of Abelyashev *et al.*[4]

The mechanism of formation of secondary echo signals and their frequencies may be explained with the symbolic formulas.[3] For example, the latest echo signal for half-integer spin I is described by symbolic formulas

$$(1^{1i}_{jj}-2^{k+1,k}_{1i}), \qquad i=2I+1, \quad k=i/2. \tag{8}$$

This means that under the action of the first pulse the initial matrix elements ρ_{jj} are transformed into the off-diagonal element ρ_{1i} that oscillates with the frequency $\omega_{1i}=-2I(\omega_n+\delta\omega_n)$. In a time interval τ between the rf pulses the quantity ρ_{1i} acquires an inhomogeneous phase $-2I(\omega_n+\delta\omega_n)\tau$. The second pulse transforms ρ_{1i} into $\rho_{k+1,k}$, that oscillates with the frequency $\omega_{k+1,k}=\omega_n+\delta\omega_n$. So, the advance of the inhomogeneous phase Φ continues, and we obtain

$$\Phi=-2I(\omega_n+\delta\omega_n)\tau+(\omega_n+\delta\omega_n)t. \tag{9}$$

Consequently, at time $t=2I\tau$ the inhomogeneous phase Φ has the same value for all the spins, and the spin echo signal appears with a carrier frequency ω_n.

SUHL–NAKAMURA INTERACTION

To take into consideration the Suhl–Nakamura interaction we used the half-classical theory of motion for nuclear spins in ferromagnets.[5] The half-classical Hamiltonian of the Suhl–Nakamura interaction may be written as

$$H_{SN}=-(1/2)\hbar\omega_p sI_-+\text{C.C.}, \tag{10}$$

where ω_p is the parameter of the interaction which coincides with the frequency pulling for homogeneous nuclear system,[6]

$$s=\langle I_+\rangle/\langle I_z^0\rangle, \tag{11}$$

$\langle I_z^0\rangle$ is the equilibrium value of $\langle I_z\rangle$. We regard a characteristic size of the inhomogeneity in the nuclear system as a small one in comparison with the correlation radius of the exchange interaction in the electron spin system.

Putting $H+H_{SN}$ into (2) we receive the integrodifferential equations for the nuclear density matrix that include $\rho(\delta\omega_n,\delta\omega_Q)$ and $\int\int\rho gd(\delta\omega_n),d(\delta\omega_Q)$. Integral terms describe the Suhl–Nakamura interaction which is "turned on" only at those time intervals when the average transverse nuclear spin $\langle I_+\rangle$ has a sufficiently large value. This effect is caused by a small characteristic size of nuclear inhomogeneity: the electron spins interact with the average nuclear spin $\langle I_+\rangle$.

In the linear approximation to the Suhl–Nakamura interaction we have received the additional echo signals that have maximum at

$$t=2p\tau, \quad 1\leqslant p\leqslant N, \tag{12}$$

where $N=2I$ for he half-integer spin, and $N=2I-1$ for the integer spin. For example, the mechanism of formation of the echo signal with maximum at $t=2\tau$ is described by symbolic formulas

$$(1^{i,i+1}_{jj}-2^{mm}_{i,i+1}-E^{i+1,i}_{mm}). \tag{13}$$

Here the first pulse transforms the diagonal matrix elements into $\rho_{i,i+1}$. In a time interval τ between the pulses the quantity $\rho_{i,i+1}$ acquires an inhomogeneous phase $\omega_{i,i+1}\tau$. The second pulse again transforms $\rho_{i,i+1}$ to diagonal elements ρ_{mm} that do not change a phase between the second pulse and the first echo signal. When the first echo signal is formed, the average transverse nuclear spin $\langle I_+\rangle$ has the maximum value. Consequently, the Suhl–Nakamura interaction is "turned on," and it transforms ρ_{mm} into $\rho_{i+1,i}$. The inhomogeneous phase advance Φ is

$$\Phi=\omega_{i+1,i}[-\tau+(t-\tau)], \tag{14}$$

and the spin echo appears at $t=2\tau$.

In conclusion we note that for $\omega_Q=0$ all secondary signals except the signal at $t=2\tau$ disappear. It means that other signals at even values t/τ are caused by both the Suhl–Nakamura and the quadrupole interactions.

A Mössbauer effect study on the acicular cobalt ferrite particles

J. G. Na
Korea Institute of Science and Technology, Sungbuk, Seoul 136-791, Korea

D. H. Han, J. G. Zhao, and H. L. Luo
State Key Laboratory of Magnetism, Institute of Physics, CAS, Beijing 100080, People's Republic of China

The causes of the coercivity enhancement and the coercivity instability of acicular cobalt ferrite particles containing 0–9.2 wt % Fe^{2+} ions under the influence of magnetic field and temperature were investigated by means of transverse magnetic field annealing, torque, and Mössbauer experiments. The coercivity enhancement and the instability of Co modified iron oxide particles are closely related to the uniaxial magnetic anisotropy. A Fe^{2+}-CO^{2+} pair model was proposed to explain the uniaxial magnetic anisotropy of Co modified iron particles. To verify the nature of the Fe^{2+}-Co^{2+} pair, the probability of one or more Co ions appearing in the neighborhood of a B site Fe^{2+} ion was calculated using the chemical composition, the Mössbauer parameters, Pi(Fe_2^+) and Pi(Fe^{+3}) and discussed conditions for forming the pair between the nearest-neighbor Co^{2+} and Fe^{2+} ion.

I. INTRODUCTION

Cobalt modified iron oxide particles are the predominant materials for use in video tapes and disks for high density digital recording density, but there are still some problems to be addressed. For cobalt body doped iron oxide particles, the coercivity decreases irreversibly with temperature and time in a magnetic field. On the other hand, the coercivities of cobalt surface doped or adsorbed iron oxide particles cannot increase significantly, usually from 600 to 800 Oe, compared to 2000 Oe for cobalt body doped ones.[1,2] Therefore, it is important to investigate the mechanism of the coercivity enhancement and the coercivity instability of cobalt modified iron oxide particles.

In this article, a Co^{2+}-Fe^{2+} model was proposed to explain the results of the transverse magnetic field annealing and the torque experiments of cobalt modified iron oxide particles. Also calculated was the probability of one or more Co^{2+} ions appearing in the neighborhood of a B site Fe^{2+} ion using Mössbauer parameters, Pi(Fe^{+}) and Pi(Fe^{+3}) to verify the nature of the Co^{2+}-Fe^{2+} pair.

II. EXPERIMENTAL PROCEDURE AND RESULTS

A. Preparation of samples

Cobalt body doped iron oxide particles were prepared by coating acicular γ-Fe_2O_3 particles (an average length of 0.5 μm, an aspect ratio of 10) with about 3.5 wt % Co^{2+} and different Fe^{2+} contents by the usual chemical coprecipitation method and then heated at 390 °C in N_2 atmosphere for 2 h for diffusing Co^{2+} and Fe^{2+} ions into the core of γ-Fe_2O_3 particles. The powders were mixed with the organic resin ink and coated on a plastic film in the presence of external magnetic field at room temperature (denoted A_1–A_6). A magnetic field of 2 kOe applied an in-plane direction of the sheets and the direction was fixed during magnetic drying. For comparison to the body doped particles, surface epitaxial iron particles were also prepared. Detailed procedures for preparing these particles were described elsewhere.[3] Magnetic tapes using these particles were made by the same process above except the heating (denoted B).

Table I represents the composition of samples A_1–A_6 and B analyzed by an inductive coupled plasma method.

B. Magnetic measurement

Magnetic properties of samples were measured using a vibrating sample magnetometer (Princeton model 155).

The coercivity instability of the sheets was measured using the method proposed by Eiling.[2] The oriented particulate magnetic sheets were put in a magnetic field of 3 kOe perpendicular to the sheet plane and annealed at 85 °C for 12 h (denoted $A_1' - A_6'$ and B'). The coercivities measured parallel to the orientation direction of the samples before and after the transverse magnetic annealing (TMA) were denoted as $H_{c\parallel}$ and $H_{c'\parallel}$ and that perpendicular to the plane of the samples as $H_{c\perp}$ and $H_{c'\perp}$, respectively. The results are listed in Table II.

The torque curves of the sheets were measured using a TOEI torque magnetometer. The detailed procedure to measure the uniaxial magnetic anisotropy constant, K_u and the crystalline magnetic anisotropy constant, K_l of the acicular cobalt ferrite particles is presented elsewhere.[4] Table III represents the K_u and K_l before and after TMA.

C. Mössbauer spectrum measurement

The Mössbauer equipment used is an electromagnetically driven, constant acceleration Mössbauer spectrometer. The radioactive source is Co(Rh) of 20 mCi. The γ-ray propagation direction was perpendicular to the plane of the samples. The Mössbauer curves of the samples before and after TMA were taken at room temperature. The Mössbauer parameters were deduced from the Mössbauer spectra by the

usual least-squares fitting techniques, using a computer. The spectra were fitted assuming two magnetic components: Fe^{+3} on the A sites, Fe^{+2} and Fe^{+3} on the B sites.

The Mössbauer spectra of sample A_4, and B were taken because the Fe^{2+} ion content of these samples is significantly different. Figure 1 shows the Mössbauer spectra of sample A_4, and B and Table IV represents the Mössbauer parameters deduced from these spectra. The Mössbauer spectra of samples before TMA are presented in Fig. 1 because there were no significant differences between the spectra of samples before and after TMA.

According to the theory of the hyperfine field of transition metal ions[5,6] and the Mössbauer parameters given in Table IV the value of $\langle N_d\rangle_{exp}$, $Pi(Fe^{+2})$ and $Pi(Fe^{+3})$ can be calculated from the following equations

$$\langle N_d\rangle = \langle N_d\rangle_{Fe^{3+}}(H_F)_{exp}/H_F(Fe^{3+}), \quad (1)$$

where $\langle N_d\rangle_{exp}$ is the local average number of the d electron with unpaired spins, $\langle N_d\rangle_{Fe^{3+}}$ unpaired d-electron number of Fe^{3+} ions, which is 5, $H_f(Fe^{3+})$ the hyperfine field of Fe^{3+} ions, which is equal to 517 kOe.[6]

$$(H_F) = P(Fe^{2+})H_F(Fe^{2+}) + P(Fe^{3+})H_F(Fe^{3+}), \quad (2)$$

where $Pi(Fe^{+2})$ and $Pi(Fe^{+3})$ are normalized probabilities for the admixture of Fe^{2+} and Fe^{3+} ions.

The calculated $\langle N_d\rangle$ and Pi are also given in Table IV.

III. DISCUSSION

From Tables I and II, it may be seen that the coercivity of cobalt body doped iron particles (A_i) increased linearly with increasing Fe^{2+} content, although the Co content of these samples was the same at about 3.5 wt %. The K_u of samples A_i increased with increasing Fe^{2+} content, while K_l of these samples decreased, as seen in Table III. These results are in good agreement with that of Wang *et al.*[7] They reported that the H_c of cobalt body doped particles increased with increasing Fe^{2+} content, which was attributed to the increase of K_u.

From the changes of the coercivities and the magnetic anisotropies of the before (A) and after (A') TMA, given in Tables II and III, one can see that the $H_{c\parallel}$ of samples decreases significantly with increasing Fe^{2+} content, while the $H_{c\perp}$ increases slightly with TMA, and this is mainly attributed to the decrease of K_u with TMA. From the above experiments, one may understand that the coercivity and the coercivity instability of cobalt modified iron particles are strongly dependent on the uniaxial anisotropy and are closely related to the Fe^{2+} ions as well as the Co^{2+} ions. These results cannot be explained by the model proposed by Kishimoto[8] and Sharrock.[9] They reported that the uniaxial

$B(B)$	0.60	441	8.7	4.3	0.4	0.6

anisotropy of cobalt ferrite powders was closely related to the coercivity instability but induced by the migration of Co^{2+} ions in a spinel lattice, and Fe^{2+} ions facilitated the migration of cobalt ions only.

On the basis of these results, we suggest that the uniaxial magnetic anisotropy of cobalt modified iron particles would be originated from the arrangement of Fe^{2+} ions with Co^{2+} ions, i.e., Fe^{2+}-Co^{2+} pair.

The Mössbauer parameters of magnetic sheets A_4 and B before TMA, given in Table IV, are comparable to those of other's works.[9] There is no significant change in the $\langle N_d \rangle_{exp}$, Pi($Fe^{+2}$) and Pi($Fe^{+3}$) between samples A_4 and B except the values of Pi(Fe^{+2}) and Pi(Fe^{+3}) in the A site. The difference of these values may be attributed to the different Fe^{2+} content of samples A_4 and B. From the values of Pi(Fe^{+2}) and Pi(Fe^{+3}) of subspectra, it may be deduced that the subspectra (A) of samples are mainly attributed to Fe^{3+} ions and the subspectra (B) to Fe^{2+} and Fe^{3+} ions. The higher the value of IS and area ratio in the B subspectrum of sample B than those of A_4, is attributed to the higher the Fe^{2+} content of sample B than that of A_4.

The probability of n-Fe ions appearing in the neighborhood of a B site Fe ion may be calculated from the following equation[10]

$$P(n) = {}_6C_n C^n (1-C)^{6-n}, \tag{3}$$

where C is the concentration of Fe ions on B sites in the spinel lattice.

Substituting $C=0.91$ in Eq. (5), the concentration of Fe in sample A_4, $P(n)$ for $N=6$, 5, 4, and 3 were obtained. $P(n)$ was calculated as 0.57, 0.34, 0.08, and 0.01 for $n=6$, 5, 4, and 3, respectively. The probability of one or more Co^{2+} ions appearing in the neighborhood of a B site Fe ion is 0.43 and that of a B site Fe^{2+} ion is about 0.25, calculated using the values of Pi(Fe^{+2}) and Pi(Fe^{+3}) in the B subspectrum of sample A_4. We did not calculate the probability for sample B because sample B was prepared using Co surface epitaxial particles. However, the probability of this sample might be higher than that of sample A_4, because of the higher Fe^{2+} content and confinement of Co^{2+} and Fe^{2+} ions to surface epitaxial layer of iron particles of sample B.

It is thought that these Co^{2+}-Fe^{2+} arrangements may form the Co^{2+}-Fe^{2+} pairs, but the appearance of Co ions in the neighborhood of the B site Fe^{2+} is only a requisite condition for forming the Co^{2+}-Fe^{2+} pair because more than a Co ion can appear in the neighborhood of a B site Fe^{2+} ion and more than a Fe^{2+} ion can also appear in the neighborhood of a Co^{2+} ion. Therefore, there may be another condition for forming the Co^{2+}-Fe^{2+} pair between the nearest-neighbor Co^{2+} and Fe^{2+} ion. These may include the ion-configuration around a Co^{2+} ion as well as that of a Fe^{2+} ion, and that distance between the nearest-neighbor Co^{2+} and Fe^{2+} because that is not the same due to the crystalline field.[11] Additional study on these points is suggested.

IV. CONCLUSIONS

(1) The coercivity enhancement and instability of Co modified iron oxide particles containing 0–9.2 wt % Fe^{2+} ions are closely related to the uniaxial magnetic anisotropy from the transverse magnetic annealing and torque experiments.

(2) The Fe^{2+}-Co^{2+} pair model was proposed to explain the uniaxial magnetic anisotropy of the magnetic particles.

(3) To verify the nature of the Fe^{2+}-Co^{2+} pair, the probability of one or more Co ions appearing in the neighborhood of a B site Fe^{2+} ion was calculated using the chemical composition, the Mössbauer parameters, Pi(Fe^{+2}) and Pi(Fe^{+3}).

X-ray photoelectron spectroscopy and Mössbauer study of $Ho(Fe_{1-x}Mn_x)_2$ compounds

Y. J. Tang, Y. B. Feng, and H. L. Luo
Institute of Physics, Academia Sinica, Beijing, People's Republic of China

S. M. Pan
General Research Institute for Non-Ferrous Metals, CNNC, Beijing, People's Republic of China

Cubic Laves compounds $Ho(Fe_{1-x}Mn_x)_2$ ($x=0$, 0.1, 0.2, 0.3) were investigated by XPS and Mössbauer measurements. It was found that the binding energy (BE) of compounds obtained by XPS remains almost the same for all the compounds and no chemical shift (δ) of the core-electron binding energy was found, which implies that no charge transfer takes place from Mn atoms to Fe atoms due to Mn substitution. Mössbauer study has shown that the average hyperfine fields and the deduced Fe moment decrease with increasing Mn content. It is considered that the variation of isomer shift (IS) due to Mn substitution obtained by Mössbauer measurement is mainly due to the size effect since the isomer shift (δ) for the compounds are almost linearly dependent on the volume; electron transfers seem to be of minor importance.

I. INTRODUCTION

In recent years much research has been carried out on the magnetic and magnetostrictive properties of $R(Fe_{1-x}T_x)_2$ (R=rare earth elements, T=Mn, Al, B, Ga, Si...) pseudobinary cubic Laves compounds in order to examine the substitution effect.[1-3] It was found from Mössbauer study that the isomer shift (IS) in $Dy(Fe_{1-x}T_x)_2$ (T=Al, B) compounds increases with increasing x value, which was ascribed to the $2p$ or $3p$ electrons of B or Al atoms are transferred into the $3d$ band of Fe atoms.[3] However since it was also found that the isomer shift (IS) in $R(Fe_xNi_{1-x})_2$ (R=Dy, Ho) compounds are linearly dependent on the volume of the variation of the isomer shift (IS) and was suggested to be mainly due to the size effect and is not related to the increase of the electron concentration of the system.[4] A better knowledge of these phenomena can lead to a better understanding of the substitution effect for transition metals on magnetic and magnetostrictive properties in RFe_2 compounds. X-ray and photoelectron spectroscopy (XPS) analysis can provide useful information about the energy shift of the core-electron binding energies. These energy shifts are related to the potential at the nucleus, which is approximately a function of the valence electron population and the potential due to the atoms of the environment, so detailed study on $R(Fe_{1-x}T_x)_2$ compounds by XPS can provide direct information about the charge transfer due to substitution. By Mössbauer study, the charge density $\rho(0)$ at the nucleus is measured through the isomer shift (IS). Mössbauer studies on ^{57}Fe for RFe_2 compounds have shown that even though these compounds have an identical crystallographic structure, they present several types of spectra.[5] With the direction of easy magnetization (n) along the [100] axis all iron atoms are equivalent and a simple six-line spectrum is obtained, as was observed for $HoFe_2$ and $DyFe_2$. If n is along the [111] or [110] direction, there are two magnetically inequivalent iron sites, giving rise to a spectrum superposed by two six-line patterns with population ratios 1:3 or 2:2, as observed for YFe_2, $TbFe_2$, $ErFe_2$, and $TmFe_2$ or $SmFe_2$ at low temperature. For $R(Fe_{1-x}T_x)_2$ compounds the spectrum become more complex when Fe was substituted with other elements, which is due to the existence of a range of hyperfine fields in the material occasioned by the random distribution of Fe and T atoms over the transition metal sublattice.

In the present study the chemical shift (δ) obtained by XPS and isomer shift (IS) measured by ^{57}Fe Mössbauer for $Ho(Fe_{1-x}Mn_x)_2$ ($x=0-0.3$) compounds were examined in order to reveal the substitution effect.

II. EXPERIMENT

$Ho(Fe_{1-x}Mn_x)_2$ ($x=0$, 0.1, 0.2, 0.3) compounds were arc melted in an arc furnace under high pure argon atmosphere, and annealed at 900 °C for a week under a purified argon atmosphere. The x-ray analysis showed that all samples were a single phase of cubic Laves structure ($C15$), and the lattice constant were calculated by using the (440) peak of x-ray spectra for the compounds. The Mössbauer spectra were recorded at room temperature with a conventional constant acceleration spectrometer with a ^{57}Co source in a Pd matrix. The record time for each sample is about two days and the velocity was calibrated with an α-Fe foil of 25-μm thickness. The x-ray photoelectron spectra (XPS) were obtained by an ESCALAB5 ESCA spectrometer equipped with an Al radiation source $E(K\alpha)=1486.6$ eV and with a resolution of 0.5 eV. The samples were supported in the appropriate sample holders and mounted on high vacuum feedthroughs, then argon sputtered for 15 min to ensure clean surface for examination.

III. RESULTS AND DISCUSSION

The lattice constants of $Ho(Fe_{1-x}Mn_x)_2$ ($x=0$, 0.1, 0.2, 0.3) compounds are obtained by the x-ray method and listed in Table I. They increase with increasing Mn content. The binding energy (BE) calculated from the XPS spectra are also listed in Table I. For metals, the binding energy is the minimum energy required to excite a core electron to an available unoccupied state above the Fermi level and is in-

fluenced by the chemical environment. According to charge potential model,[6] the ionization energy of a core subshell (i_A) is approximated by

$$I(i_A)=k_i^A q_A+eV_A, \tag{1}$$

where q_A is the partial charge on the atom A, k_i^A, is an adjustable parameter, and V_A is the potential of atom A due to the other atoms B in the system. With a simple point-charge approximation

$$V_A=\sum_{B\neq A}\frac{q_B}{4\pi\epsilon_0 R_{AB}}, \tag{2}$$

where the R_{AB} are internuclear distances. From analyzing the binding energy of Fe $2p_{1/2,3/2}$ and of Mn $2p_{3/2}$ listed in Table I we found that the binding energy (BE) of compounds remains almost the same value for all the compounds and no chemical shift of the core-electron binding energy was found. This implies that no charge transfer takes place from Mn atoms to Fe atoms due to Mn substitution.

The Mössbauer spectra present in Fig. 1 were analyzed using a standard computer procedure. Depending on the shape of the spectrum one to five independent six-line patterns with unrestricted intensities, hyperfine fields, quadruple splitting, and isomer shift were fitted in order to reproduce the broadening of the spectra with increasing Mn content. The half-width of all the six-line patterns was kept constant. The spectrum of $HoFe_2$ was fitted as one six-line pattern, indicating that the magnetic moment is directed along the [100] axis.[5] It is obvious that Mn substitution has a great influence on the hyperfine interaction, as can be seen from Fig. 1. The Mössbauer absorption spectra for $x>0$ compounds indicate the existence of the wide hyperfine field distribution because of the random distribution of Mn atoms in transition metal sublattice. The broadening of spectra was also found in other $R(Fe_{1-x}T_x)_2$ compounds due to substitution and was explained, for $R(Fe_{1-x}Al_x)_2$ compounds,[2] on the basis of the local environment effect which supposes that the hyperfine fields distribution for a given iron atom has a proportionality relation with the number of Fe nearest- and next-nearest-neighbors calculated from the binomial formula. However, no reasonable results can be obtained in the present study when the same procedure, as used for $R(Fe_{1-x}Al_x)_2$ compounds, was employed to fit the spectra of $Ho(Fe_{1-x}Mn_x)_2$ compounds, which means that no definite conclusion can be drawn about the existence of the local environment effect in $Ho(Fe_{1-x}Mn_x)_2$ compounds. Through fitting the spectra, the average hyperfine field H_{hf}, isomer shift (IS), and quadruple splitting (QS) are obtained and listed in Table I. It is clearly seen from Table I that the average hyperfine field decreases with increasing Mn content. It has been shown[7] from combined NMR and Mössbauer investigation that the average iron hyperfine field and average iron moment are proportional to each other

$$H_{hf}=a\mu_{Fe}. \tag{3}$$

The proportionality constant a equals 145 kOe/μ_B for Y-Fe compounds[7] and 125 kOe/μ_B was used for $Dy(Fe_{1-x}B_x)_2$ compounds.[3] Here we consider $a=137$ kOe/μ_B for $Ho(Fe_{1-x}Mn_x)_2$ compounds, which was deduced from the hyperfine field and iron moment for $HoFe_2$ in the present study. The Fe moments calculated from Eq. (3) were listed in Table I. The decrease of μ_{Fe} with increasing Mn content is evident which means that Fe moment is strongly influenced by Mn atoms.

From Table I it can also be seen that the average isomer shift (IS) shows a weak concentration dependence, which is the characteristic of these compounds. We note that the IS for the compounds are almost linearly dependent on the volume, as can be seen from Fig. 2. Taking the XPS results for the compounds into account we suggest that the variation of IS

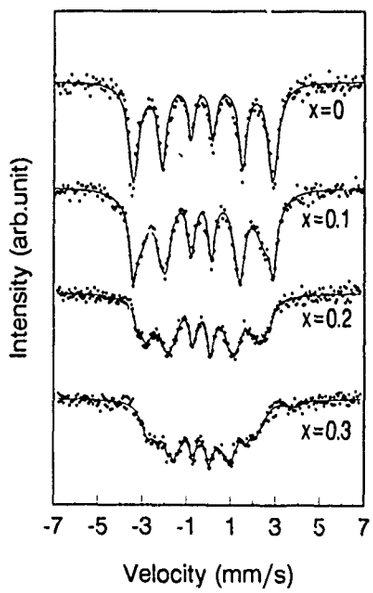

FIG 1. Mossbauer spectra of $Ho(Fe_{1-x}Mn_x)_2$ compounds ($x=0$, 0.1, 0.2, 0.3) at room temperature.

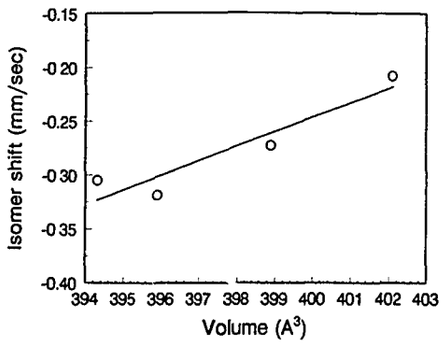

FIG. 2. Volume dependence of the isomer shift in $Ho(Fe_{1-x}Mn_x)_2$ compounds.

due to Mn substitution is mainly due to size effects; electron transfers seems to be minor importance.

IV. CONCLUSION

In conclusion, we would like to point out that for $Ho(Fe_{1-x}Mn_x)_2$ ($x=0$, 0.1, 0.2, 0.3) compounds:

(1) From the XPS measurement it was found that the binding energy (BE) of compounds remains almost the same value for all the compounds and no chemical shift (δ) of the core-electron binding energy was found, which implies that no charge transfer takes place from Mn atoms to Fe atoms due to Mn substitution.

(2) From the Mössbauer study it was found that the average hyperfine fields and the deduced Fe moment decrease with increasing Mn content. The variation of the IS due to Mn substitution is mainly due to size effects; electron transfers seem to be of minor importance.

The combined hyperfine interaction of mercury in a hexagonal close-packed cobalt single crystal was measured using the $e^- - \gamma$ perturbed angular correlation technique with the ^{197}Hg and ^{199}Hg probes, without applied magnetic field. The magnetic and quadrupole coupling constants of the $5/2^-$ levels in both ^{197}Hg and ^{199}Hg were measured with extremely high precision, ω_L(^{197}Hg)=951(9) Mrad/s, ω_L (^{199}Hg)=1039(10) Mrad/s, υ_Q (^{197}Hg)=3.7(5) MHz and υ_Q (^{199}Hg)=32(2) MHz. Using the well-known g factors and quadrupole moments of the respective levels, the magnetic hyperfine field, $|H_{hf}(\underline{\text{Hg}}\text{Co})|$=581(12) kG, and the electric field gradient, $|V_{zz}(\underline{\text{Hg}}\text{Co})| = 2.0(3)\times10^{17}$ V/cm^2, were derived. The importance of using these hyperfine probes for studying the microscopic structure of cobalt-based multilayers is introduced and discussed.

I. INTRODUCTION

The potential applications of the giant magnetoresistance effect in recent years led to a considerable interest of magnetic multilayers consisting of a magnetic material, usually cobalt, separated by a thin nonmagnetic spacer. The optimization of the effect depends on the thickness, structure, and interface properties of the spacer and Co layers. Using the ^{111}Cd nucleus from the decay of ^{111}In as a probe implanted in Co/Re and Co/Cu multilayers,[1,2] the perturbed angular correlation (PAC) technique proved to be sensitive for the microscopic characterization of structural and point defects, phases, and interfaces in magnetic multilayers. The application of this technique is, however, limited to suitable probes. In the present work, it is shown that the ^{197m}Hg and ^{199m}Hg isotopes are appropriate for these studies: the hyperfine fields are higher and the substitutional fraction of Hg implanted in Co is a factor of three higher than in the Cd case, with no need to perform annealing treatments after the implantation.

The magnetic hyperfine interaction of Hg in Co has been previously studied by Krien and co-workers.[3] Their measurement could not, however, explain if the Hg atoms are at different sites in the Co lattice or if a combined hyperfine interaction is responsible for the observed modulation, since a quadrupole interaction is expected for the Co hexagonal close-packed (hcp) phase. To clarify this problem, new results are reported here, using the $e^- - \gamma$ PAC technique with the ^{197m}Hg and ^{199m}Hg isotopes, in a Co single crystal. The lattice site location of the Hg atoms has also been studied by a high precision channeling experiment performed after the radioactive decay on the same sample.

II. EXPERIMENTAL DETAILS

The ^{197m}Hg and ^{199m}Hg isotopes were implanted into a Co single crystal at 60 keV, using the ISOLDE facility at CERN, to doses of 5×10^{13} and 5×10^{12} at./cm^2, respectively. The mean-Hg range profile value is 11 nm.

The PAC experiments were performed using the 165–134 keV cascade from the decay of the 23.8-h isomeric state of ^{197}Hg, and the 374–158 keV cascade from the decay of the 43-min isomeric state of ^{199}Hg. The first transitions in these cascades are strongly converted, α_L(165 keV, ^{197}Hg)=173 and α_K(374 keV, ^{199}Hg)=3.5, which makes them ideal for e^--γ measurements. The calculated anisotropies are b_2A_{22}(^{197}Hg)=0.213 and b_2A_{22}(^{199}Hg)=0.235.[4]

The experimental setup consists of two magnetic β spectrometers of the Siegbahn type[5] for detection of conversion electrons and two BaF_2 scintillators for γ detection, arranged in a plane. Each lens makes 90° with one γ detector and 180° with the other. The time resolution (FWHM) of the setup for the ^{197m}Hg and ^{199m}Hg cascades was 1.0 ns. Four coincidence spectra were recorded, corresponding to the combinations of each magnetic lens with a γ detector. From these spectra the usual time differential anisotropy $R(t)=2\,[N(180°, t)-N(90°,t)]/[N(180°,t) + 2\,N(90°,t)]$ was calculated.

The theoretical $R(t)$ function was calculated numerically taking into account the full Hamiltonian for a combined hyperfine interaction, as described by Barradas and co-workers.[6] In the calculation, independent fractions f_i of probe nuclei were considered, each experiencing a Larmor frequency, $\omega_L = -g\mu_N H_{hf}/\hbar$ and a quadrupole frequency, $\upsilon_Q = eQV_{zz}/h$. H_{hf} is the magnetic hyperfine field and V_{zz} is the main component of the electric field gradient (EFG) tensor at the nucleus. Q and g are, respectively, the quadrupole moment and g factor of the $I=5/2$ intermediate state of the cascade. For ^{197}Hg and ^{199}Hg these parameters are well known, $Q_{5/2^-}$ (^{197}Hg)=0.057(7) b, $Q_{5/2^-}$(^{199}Hg)=0.674(77) b,[7,8] $g_{5/2^-}$(^{197}Hg)=0.342(6), and $g_{5/2^-}$(^{199}Hg)=0.352(13).[9] Lattice imperfections, impurities, or defects cause a damping of the $R(t)$ function, described by a Lorentzian distribution with relative width δ, centered at a given ω_L.

No external magnetic field was necessary to orient the magnetic domains, since below 525 K the spins of the hcp Co lattice are aligned along the c axis. This is also the direction of the main component of the EFG tensor. For each isotope, experiments were performed on two complementary

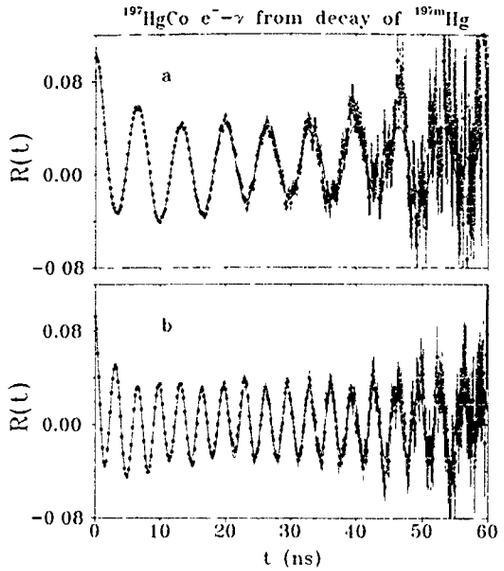

FIG. 1. Anisotropy ratios obtained with ^{197}Hg for (a) single crystal with c axis on the detectors' plane at 45°; (b) with c axis perpendicular to the detectors' plane.

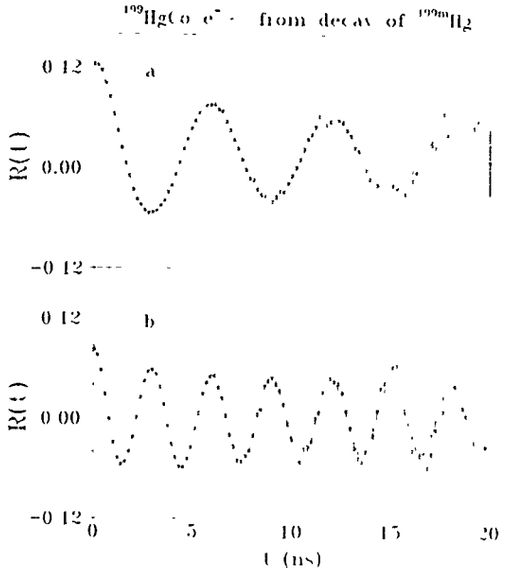

FIG. 2. Anisotropy ratios obtained with ^{199}Hg for (a) single crystal with c axis on the detectors' plane at 45°; (b) with c axis perpendicular to the detectors' plane.

geometries. In geometry G1 the c axis of the Co-single crystal lies on the detectors' plane at an angle of 45° with the detectors, and in geometry G2 it is perpendicular to that plane. For a collinear interaction, only the $\omega_L \pm 2\omega_0$ and $2\omega_L \pm \omega_0$ frequencies ($\omega_0 = 3\pi\upsilon_Q/10$) have observable amplitudes in geometries G1 and G2, respectively.

Complementary RBS/channeling experiments were carried out after the ^{197m}Hg decay in the channeling line of the 2.5-MeV Van de Graaff of INETI, Sacavém, using a 1.6-MeV He^+ beam. The backscattered particles were detected at angles of 140° and 180° using two silicon surface barrier detectors with resolutions of 13 and 18 keV, respectively.

III. RESULTS

Figures 1(a) and 1(b) show the anisotropy ratios $R(t)$ obtained with the ^{197m}Hg implanted sample in geometries G1 and G2, respectively. The measurements have been performed at room temperature. Assuming the Hg ions are substitutional in the Co lattice they would experience only one combined interaction, described by a theoretically predicted modulation. However, to obtain a satisfactory least-squares fit to both geometries, it was necessary to consider that the Hg atoms are located in three nonequivalent Co lattice sites. The results are shown in Table I. Parameter f_1 gives the percentage of Hg atoms described by a theoretical function assuming well-defined magnetic and electric frequencies. Parameter f_2 corresponds to Hg atoms characterized by the same values for the frequencies, but with a small Lorentzian distribution on the magnetic frequency. The remaining Hg atoms are described by a strongly damped frequency distribution, characterized by a large value of δ.

Figures 2(a) and 2(b) show the corresponding anisotropy ratios, $R(t)$, obtained with the ^{199m}Hg implanted sample. Again, it was necessary to consider three fractions of Hg atoms in the Co lattice. The results are shown in Table II.

Figure 3 shows the angular scans obtained for the (0001) plane (c plane) and for the $\langle 11\bar{2}0\rangle$ and $\langle 10\bar{1}0\rangle$ axes along that plane. From the minimum yields of the Hg and Co signals, a fraction of 70% of Hg atoms in regular positions in the Co single crystal is obtained. The slight narrowing of the Hg signal, clearly seen in the (0001) plane and in the $\langle 10\bar{1}0\rangle$ axis, indicates a fraction of Hg ions deviated from the substitutional positions. The continuous line in Fig. 3 is a Monte Carlo simulation of these scans, using a modified version of the FLUX program,[10] assuming a 50% substitutional fraction, a 20% slightly deviated fraction, and a 30% random fraction. The errors in the determination of these fractions are of the order of 10%.

IV. DISCUSSION AND CONCLUSIONS

The PAC experiments show the surprising result that about 75% of the implanted probe atoms (fractions f_1 and f_2) stop at regular sites, and the channeling experiment proves that the Hg atoms are substitutionally located in the Co matrix. The observed frequency distribution of fraction f_2 is small and the modulation could be followed for about eight half-lives of the intermediate state of the cascades. This is due to the fact that the magnetic coupling constant is much higher than the quadrupole coupling constant.

Although the quadrupole coupling constants are very small, as a consequence of the small deviation for Co of the c/a=1.6228 ratio from the ideal value (c/a=1.633), in this work they were derived very accurately: υ_Q (^{197}HgCo)=3.7(5) MHz and υ_Q (^{199}HgCo)=32(2) MHz. From the value of υ_Q(^{199}Hg Co) and the corresponding quadrupole moment, the derived EFG is $|V_{zz}$(Hg Co)|=2.0(3)$\times 10^{17}$ V/cm^2. According to known trends[11] its sign should be negative. In Ref. 3, the ionic EFG produced by the Co ions at the Hg-probe nucleus has been calculated as $V_{zz}^{\text{ion}}=+1.14\times 10^{17}$ V/cm^2. The enhancement of the ionic EFG by the conduction electrons is usually described by a factor K, as $V_{zz}=(1-K)\ V_{zz}^{\text{ion}}$. For the present case we deduce $K=2.8$ which is of the same order as for most cases.

An important result of this work is the derivation of a more precise value for the magnetic hyperfine coupling constant measured by the Larmor frequency ω_L(^{197}Hg Co)=951(9) Mrad/s. Due to the high statistics obtained in these measurements, the errors in the magnetic frequencies are limited only by the 1% uncertainty of the time calibration. Using the known g factor, $g_{5/2}$-(^{197}Hg)=0.342(6),[9] the derived magnetic hyperfine field is $|H_{hf}$(HgCo)|=581(12) kG, which fits very well in the systematic of hyperfine fields in Co.[12]

In conclusion, the ^{197}Hg and ^{199}Hg are very attractive probes for the study of Co-based structures using the PAC technique, due to the high substitutionality in Co achieved after implantation at room temperature. Additionally, the availability of two isotopes with quadrupole moments differing by one order of magnitude allows a great flexibility for the study of EFGs. Since the EFGs at the Hg site in the interfaces, or at the Co site with trapped defects or impurities, are normally much higher than the EFG of Hg in Co, a large range of values can be measured selecting the appropriate probe, ^{197}Hg or ^{199}Hg, for the high or low range of EFGs. These advantages are currently being explored at ISOLDE/CERN due to the high yields for the production of these isotopes.

Simulation of nuclear magnetic resonance spin echoes using the Bloch equation: Influence of magnetic field inhomogeneities

J. A. Nyenhuis and O. P. Yee
School of Electrical Engineering, Purdue University, West Lafayette, Indiana 47907

There are a number of low cost nuclear magnetic resonance (NMR) applications that are based on measurements of spin-spin (T_2) and spin-lattice (T_1) relaxation times. Pulsed rf magnetic fields are typically used to flip the nuclear spins in these measurements. The ability to perform these measurements in relatively nonuniform magnetic fields is a factor in minimizing costs. In this work, we explore the limitations of field inhomogeneity on spin echo techniques for measuring relaxation times. Using a computer model that was developed for this study, we numerically integrate the Bloch equation to simulate spin echo peaks for CPMG and other pulse sequences. We quantify how higher intensity rf pulses result in increased amplitudes of spin echo peaks in an inhomogeneous static magnetic field. An rf amplitude which is five times the maximum inhomogeneity in the static field results in less than 0.5% attenuation between even numbered peaks in a CPMG sequence.

I. INTRODUCTION

Numerous applications of nuclear magnetic resonance (NMR) have been developed; for example, it has been proposed that NMR be used to sort fruits and vegetables,[1] to measure the percentage of saturated fats in vegetable oils,[2] and for the early detection of osteoporosis in humans.[3]

NMR techniques have several advantages over other methods of experimental analysis; they are neither destructive nor invasive to the sample under study. Ultimately, however, it is cost and not these advantages, which will determine whether NMR can compete with experimental methods already in place. A major factor affecting the cost of a NMR system is the magnet. Magnets that produce highly uniform magnetic fields are difficult to manufacture and, correspondingly, are expensive.

This paper investigates the effects of nonuniform magnetic fields on spin echo techniques for measuring relaxation times. We seek to answer the question: how uniform must the fields be in order to achieve good measurements?

II. SIMULATION MODEL

A computer model, written in FORTRAN, of NMR phenomena was developed for this study. The assumptions made in this model are (1) a one-dimensional model is used, (2) the sample is magnetically homogeneous, (3) the applied rf fields are uniform across the sample, and (4) diffusion effects are ignored. These assumptions are made in order to isolate the effects of nonuniform magnetic fields and are not limitations of the computer model.

In the simulation model the sample is divided into regions of magnetization $\mathbf{M}_i=(M_x,M_y,M_z)$, which represent the vector sum of all magnetic moments in the region.

The number of regions used in the simulations was 2499, although a choice as low as 99 regions would yield comparable results. For a sufficiently large number of regions, the solutions are basically independent of the number of regions, because the magnetization in each region is independent of that in another region; however, if diffusion is included in the model, magnetization in one region is coupled to adjoining regions, and the accuracy of solutions improves by increasing the number of regions. The number of regions chosen must be large enough, however, to obtain a good sampling of the dephased spins in an inhomogeneous magnetic field.

An rf field of carrier frequency ω_0 with only x and y components is assumed: $\mathbf{h}_{\rm rf}=(h_x,h_y)$. The static field is assumed to lie in the z direction and has an amplitude $H_0+\Delta H_i$, where $H_0\equiv\omega_0/\gamma$, with γ being the nuclear gyromagnetic constant. H_0 is thus the field for which the resonance frequency is equal to the rf frequency and ΔH_i accounts for inhomogeneity in the static field.

The time evolution of each region's M_i in response to the static and rf magnetic fields is given by the Bloch equation

$$\frac{d\mathbf{M}_i}{dt}=\gamma\{\mathbf{M}_i\times[(H_0+\Delta H_i)\hat{\mathbf{z}}+\mathbf{h}_{\rm rf}]\}-\frac{M_{x,i}}{T_{2,i}}\hat{\mathbf{x}}-\frac{M_{y,i}}{T_{2,i}}\hat{\mathbf{y}}-\frac{M_{z,i}-M_{0,i}}{T_{1,i}}\hat{\mathbf{z}}, \tag{1}$$

where $M_{0,i}$ is the saturation magnetization in the presence of the static field.

In Eq. (1), the subscript i indicates that the Bloch equation is applied separately to each region in the sample.

The normalized magnetization in a region is expressed as $\mathbf{m}_i=\mathbf{M}_i/M_{0,i}$, where $M_{0,i}$ is the saturation magnetization in that region. Magnetic fields are normalized to the value of static field for which the nuclear spins have resonance frequency ω_0, e.g., $\tilde{\mathbf{h}}_{\rm rf}=\mathbf{h}_{\rm rf}/H_0$. Time is normalized to cycles of the rf field, e.g., $\tilde{t}=\omega_0 t/(2\pi)$.

Transforming Eq. (1) into a coordinate frame[4] that rotates at the rf field frequency ω_0, and letting $\tilde{H}_{{\rm eff},i}\equiv\Delta H_i/H_0$, the normalized Bloch equation in component form for each region is

$$\begin{aligned}
\frac{dm_{x,i}}{d\tilde{t}}&=2\pi(\tilde{H}_{{\rm eff},i}m_{y,i}-\tilde{h}_{y,i}m_{z,i})-\frac{m_{x,i}}{\tilde{T}_{2,i}},\\
\frac{dm_{y,i}}{d\tilde{t}}&=2\pi(\tilde{h}_x m_{z,i}-\tilde{H}_{{\rm eff},i}m_{x,i})-\frac{m_{y,i}}{\tilde{T}_{2,i}},\\
\frac{dm_{z,i}}{d\tilde{t}}&=2\pi(\tilde{h}_{y,i}m_{x,i}-\tilde{h}_{x,i}m_{y,i})-\frac{m_{z,i}-1}{\tilde{T}_{1,i}}.
\end{aligned} \tag{2}$$

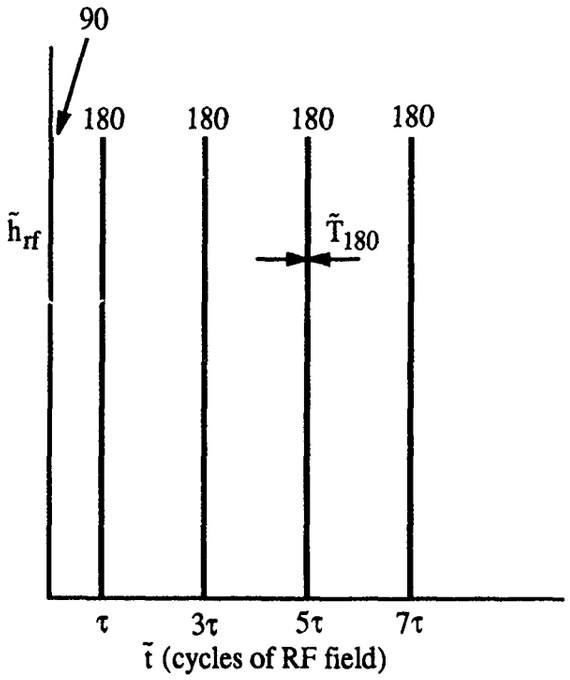

FIG. 1. rf pulse sequence used in the spin echo simulations.

The Bloch equation is now in the form of three first-order differential equations that are solved numerically for each region in the sample. The simulations implement the fourth-order Runge–Kutta method with a step time of five cycles of the rf field. This step time was chosen because it was a large enough step that excessive computing time was not required and at the same time the solutions would converge to five decimal places.

For the case when the rf signal is turned off, simple closed form expressions[5] for the magnetization components exist, which reduces the computational time of the simulations.

After each time step in the simulation, the transverse magnetization components, $m_{x,i}$ and $m_{y,i}$, are summed vectorially over all the regions in the sample. The receiver coils in a NMR system will detect signals proportional to the transverse magnetization of the sample. The receiver flux, normalized to the maximum possible value when all the spins are in phase, is then

$$\text{Normalized receiver response} = \left(1 \Big/ \sum_i M_{0,i}\right) \times \sqrt{\left(\sum_i M_{0,i} m_{x,i}\right)^2 + \left(\sum_i M_{0,i} m_{y,i}\right)^2}. \quad (3)$$

III. SIMULATION RESULTS AND DISCUSSION

The rf pulse sequence used in the simulations is shown in Fig. 1. A 90° rf pulse cants the nuclear magnetization from the z direction into the transverse plane. 180° pulses are used to generate the spin echoes, which result from refocusing of the spins after the 180° pulse. The 90° rf pulse is taken to be in the x direction in the rotating frame. For a Carr–Purcell–Meiboom–Gill[6] (CPMG) pulse sequence, the 180° pulses are in the y direction, while they are in the x direction for a Carr–Purcell[7] (CP) pulse sequence. With the 180° pulses depicted, spin echoes occur near times 2τ, 4τ, 6τ, and 8τ. Amplitude $\tilde{h}_{rf}$ and durations $\tilde{T}_{90}$ and $\tilde{T}_{180}$ of the rectangular rf pulses were varied for different simulations. From Eq. (2), it can be shown that for a 90° flip $\tilde{T}_{90}=1/4\tilde{h}_{rf}$ and $\tilde{T}_{180}=2\tilde{T}_{90}$.

A linear inhomogeneity was assumed for the simulation results presented here:

$$\Delta H_i = \Delta H_{max} x_i / L \quad -L \leq x_i \leq L. \quad (4)$$

For the results presented here, the normalized inhomogeneity $\Delta\tilde{H}_{max}=\Delta H_{max}/H_0$ was 5×10^{-4}, i.e., 500 ppm. This inho-

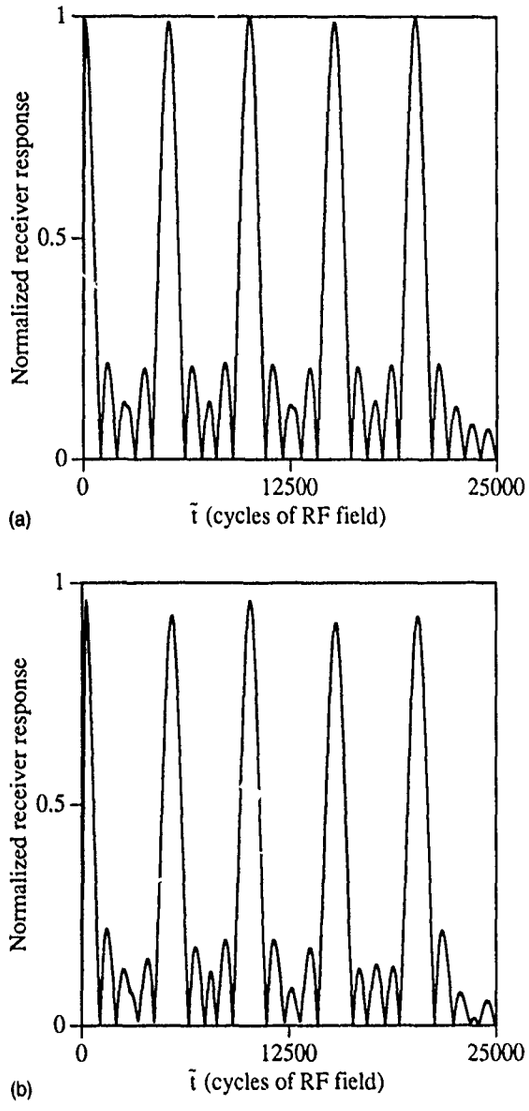

FIG. 2. Effect of rf amplitude on spin echo amplitudes. A CPMG rf pulse sequence was used for a linear inhomogeneity with $\Delta\tilde{H}_{max}=500$ ppm and $\tau=2500$ cycles. $\tilde{T}_1=\tilde{T}_2=10^{12}$ cycles of rf field in the model. (a) $\tilde{h}_{rf}=2.5\times10^{-3}$ and $\tilde{T}_{180}=2\tilde{T}_{90}=200$ cycles. Response peaks are 0.9933, 0.9873, 0.9985, 0.9873, and 0.9946. (b) $\tilde{h}_{rf}=10^{-3}$ and $\tilde{T}_{180}=500$ cycles of rf field. Response peaks are 0.9610, 0.9260, 0.9590, 0.9087, and 0.9236.

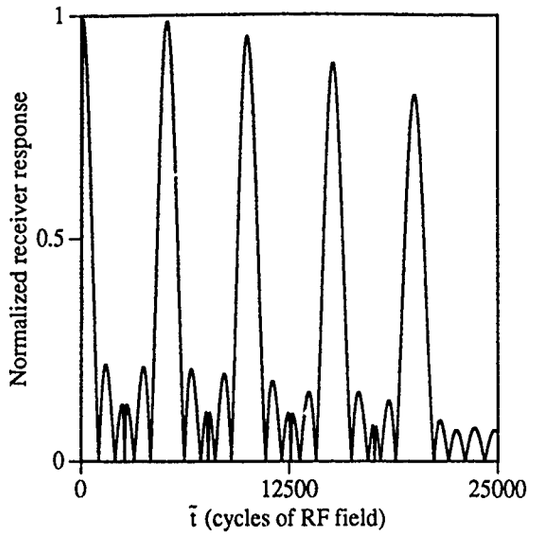

FIG. 3. Effect of using CP rf pulse sequence on spin echo simulations. rf pulse amplitude $\tilde{h}_{rf}=2.5\times10^{-3}$ ($\tilde{T}_{90}=100$ cycles of rf field) and a linear inhomogeneity with $\Delta\tilde{H}_{max}=500$ ppm was used. $\tau=2500$ cycles and $\tilde{T}_1=\tilde{T}_1=10^{12}$ cycles of rf field. Response peaks are 0.9933, 0.9864, 0.9514, 0.8905, and 0.8195.

mogeneity is of the order of magnitude that is experienced in low cost NMR applications. However, spectrometers and medical imagers use magnets with much better homogeneity. The normalized relaxation times $\tilde{T}_1$ and $\tilde{T}_2$ were arbitrarily set to a large value of 10^{12} cycles. With the effects of nuclear relaxation essentially removed from the calculations, we could focus on the effects of inhomogeneity in the static field on the spin echo response.

In Fig. 2, we evaluate the effect of rf amplitude on the echo peaks for a CPMG sequence. In Fig. 2(a) a rf field with amplitude $\tilde{h}_{rf}=2.5\times10^{-3}$ is used, which results in a normalized duration $\tilde{T}_{180}=200$ cycles. As is expected for the CPMG pulse sequence, even echo peaks have the greatest height, and the fourth peak in the sequence has normalized amplitude 0.9946. In Fig. 2(b), the rf field amplitude has been reduced to $\tilde{h}_{rf}=10^{-3}$, and the 180° pulse has a duration of 500 cycles. Compared to the case for $\tilde{h}_{rf}=2.5\times10^{-3}$, the echo peaks have a smaller amplitude, with the fourth peak having an amplitude of 0.9236.

The reduction between even numbered peaks in a spin echo sequence is used to determine T_2 in a CPMG sequence: normalized receiver response $\propto\exp(-t/T_2)$. For an accurate T_2 measurement, we would like the attenuation, due to magnetic field inhomogeneity, between even peaks to be much less than the attenuation due to spin-spin relaxation. For Fig. 2(a), the reduction in signal between the even peaks corresponds to an effective spin-spin relaxation time $\tilde{T}_{2,eff}$ of 2.6×10^6 cycles, whereas in Fig. 2(b) $\tilde{T}_{2,eff}$ is 0.27×10^6 cycles. Thus, the higher intensity rf field results in a more accurate T_2 measurement. Less effect of the inhomogeneity could also be achieved by increasing τ. For instance, increasing τ to 5000 cycles, but maintaining the other conditions of Fig. 2(a), results in $\tilde{T}_{2,eff}$ of 6.2×10^6 cycles. For $\tau=7000$ cycles, $\tilde{T}_{2,eff}=8.5\times10^6$ and for $\tau=9000$ cycles, $\tilde{T}_{2,eff}=10.6\times10^6$.

An intuitive argument can be made to explain why shorter (i.e., higher intensity) rf pulses result in higher echo peaks in a CPMG sequence. With inhomogeneity in the static field, nuclear spins will have precession frequencies different from the frequency of the rotating rf field. Assume that the direction of the rf field is fixed in the rotating frame. The azimuthal angle of the nuclear magnetization will rotate at frequency $\Delta\omega=\gamma\Delta H_t$ with respect to the direction of the rf field. Let $\Delta\phi_{180}$ represent the change in angle during the 180° pulse between the rf field and the transverse component of nuclear magnetization:

$$\Delta\phi_{180}=\Delta\omega T_{180}=\gamma\Delta H_{max}T_{180}$$
$$=2\pi\Delta\tilde{H}_{max}\tilde{T}_{180}=\pi\Delta\tilde{H}_{max}/\tilde{h}_{rf}. \quad (5)$$

If there is significant change in angle between the rf field and the nuclear spins during a rf pulse, the flip angle will not have the desired value. For spin echo peaks with maximal value, we thus expect $\Delta\phi_{180}\ll1$. For $\tilde{h}_{rf}=2.5\times10^{-3}$ in Fig. 2(a), $\Delta\phi_{180}=0.63$ and for $\tilde{h}_{rf}=10^{-3}$ in Fig. 2(b), $\Delta\phi_{180}=1.57$.

Figure 3 shows a spin echo sequence using the same conditions as in Fig. 2(a), except that both the 90° and 180° pulses are in the x direction. For this CP sequence, the echo peaks progressively decrease in amplitude, with the fourth peak having an amplitude of 0.8195. Comparison of Figs. 2(a) and 3 clearly shows the advantage of the CPMG over the CP sequence in an inhomogeneous field. In the CMPG sequence, deviations from the ideal flip between successive 180° pulses are partially compensated, whereas errors in flip angle accumulate in the CP sequence.[8]

The CPMG sequence is forgiving of imperfections in rf pulse duration. The parameters of Fig. 2(a) were maintained, but $\tilde{T}_{90}$ and $\tilde{T}_{180}$ were independently made 10% too long. The amplitudes of the fourth echo peaks were then respectively 0.9829 and 0.9840, only slightly less than those shown in Fig. 2(a).

Correlation of magneto-volume effects and local properties of the Fe_2Ti-laves phase (abstract)

J. Pelloth, R. A. Brand, and W. Keune
Laboratorium für Angewandte Physik, Universität Duisburg, D-47048 Duisburg, Germany

Magneto-volume effects have been calculated[1] and shown to exist[2,3] in Fe_2Ti alloys. Since Mössbauer spectroscopy provides insight into local magnetic properties we have performed such measurements in the temperature range 4.2 K$<T<$800 in $B_{ext}=0$ and $\neq 0$ on $Fe_{2+x}Ti_{1-x}$ powder samples with $x=-0.05$ to $+0.1$. The spectra of Fe_2Ti at 4.2 K show two subspectra, one belonging to the antiferromagnetically coupled $6h$ sites, and the other one to the paramagnetic $2a$ sites, in agreement with Ref. 4. A detailed analysis shows that the electric field gradient of the $6h$ sites changes in sign and value when going from the antiferromagnetic to the paramagnetic state at 310 K. Moreover, the isomer shift values of the two sites are found to be different at 4.2 K, while they are equal above 310 K. Both changes suggest a change in the local electronic band structure between the paramagnetic and antiferromagnetic states. An increase of the linewidth is observable in the temperature region of 200 K$<T<$310 K that could be caused by a distribution of hyperfine fields on the $6h$ sites or by spin fluctuations during the lifetime of the excited state of the Mössbauer nucleus. For $x>0$ and 4.2 K, an additional magnetically split subspectrum appears that is associated with $6h$ sites and neighboring Fe antisite atoms. For $x<0$ the spectra are similar to those of Fe_2Ti.

Giant magnetoresistance (GMR) effects are observed in several classes of bulk magnetic materials. The resistance changes at metamagnetic transitions connected with reorientation of $4f$ moments are only moderate due to the relatively weak coupling of the $4f$ and conduction electrons. Much larger GMR effects can be achieved by mechanisms involving the d states (RhFe, RCo_2), though the most spectacular resistance variations are connected with metamagnetic transitions in U-intermetallic antiferromagnets. This phenomenon can be interpreted as due to Fermi surface gapping (due to magnetic superzones) and/or due to spin-dependent scattering in analogy with magnetic multilayers.

I. INTRODUCTION

During the dramatic development in the research of magnetic multilayers, the magnetoresistance has become one of the frequently reported quantities. This originated by the discovery a large ("giant") magnetoresistance (GMR) in Fe/Cr multilayers.[1] Since then, further multilayer systems exhibiting GMR have been reported. One of the most impressive effects has been observed in Co/Cu multilayers, in which the electrical resistivity at low temperatures is reduced in magnetic field to half of its zero-field value.[2] The strong interest in GMR effects is closely connected with promising industrial applications in magnetoresistive reading heads and similar elements.

Magnetic multilayers are artificial superlattices in which the layers of atoms carrying magnetic moments are separated by nonmagnetic layers. The nonmagnetic layers mediate exchange interactions between the magnetic ones. In systems exhibiting GMR, these exchange interactions are, as a rule, antiferromagnetic. As a result we obtain antiparallel interlayer coupling. These exchange interactions are relatively weak and can be easily overcome by magnetic field and a ferromagnetic alignment of spins can be achieved in a relatively low field. A pronounced reduction of the electrical resistivity can be observed due to this transition, because the resistance in the ferromagnetic aligned is much smaller than in the antiferromagnetic case. The occurrence of GMR effects in multilayer systems is usually ascribed to the spin-dependent scattering.[3]

Magnetic-field-induced transitions in antiferromagnets have been studied in bulk materials for decades. These transitions are called metamagnetic in analogy to the metastable (metamagnetic) state which sets in above the critical field. They take place in a magnetic field sufficient to overcome the antiferromagnetic interactions and to modify the magnetic structure. The modification of the magnetic structure is frequently connected with a change of the translational symmetry and is usually accompanied by a noticeable change of the electrical resistivity.

Another type of metamagnetic transition, which is also reflected in the electrical resistivity, can be found in itinerant electron materials, which are close to a magnetic instability. This class of materials can be well represented by the RCo_2 compounds (R=rare-earth metal). Here a sufficiently large magnetic field can induce magnetic moment on Co sites[4,5] and, simultaneously, the system undergoes a transition from the paramagnetic to a magnetically ordered state.

Note that the magnetoresistance is usually defined by the expression

$$\Delta\rho/\rho=[\rho(T,H)-\rho(T,0)]/\rho(T,0), \tag{1}$$

where $\rho(T,H)$ and $\rho(T,0)$ are the resistivities at a given temperature in the actual and zero magnetic field, respectively. For the transition from the antiferromagnetic to the ferromagnetically aligned state with the resistivities ρ_{AF} and ρ_F, respectively:

$$\Delta\rho/\rho=(\rho_{AF}-\rho_F)/\rho_{AF}. \tag{2}$$

In the multilayer research it is customary to use a modified expression:

$$\Delta\rho/\rho=\{\rho_{AF}-\rho_F\}/\rho_F, \tag{3}$$

which provides naturally much more spectacular values. Unless especially mentioned, we will use the representations (1) and (2).

Here, we review the magnetoresistance effects in different classes of bulk magnetic materials with a special emphasis on single-crystal data available only very recently for lower symmetry materials. We want to demonstrate that the GMR effects are frequently observed especially in $5f$ electron intermetallics and discuss the origin of these phenomena. We will discuss also required model parameters of an intermetallic system to achieve GMR effects at conditions desirable for practical applications.

II. RESISTANCE IN METALLIC SYSTEMS

For simplicity, the resistance in metallic systems can be discussed as due to independent scattering mechanism (i.e., supposing the validity of the Mathiessen's rule):

$$\rho=\rho_0+\rho_{e-p}+\rho_{spd}. \tag{4}$$

Both the temperature independent term ρ_0 due to crystal structure imperfections and the electron-phonon scattering term ρ_{e-p} are present in all materials. In magnetic materials the scattering of conduction electrons on magnetic moments should be taken into account. This is reflected in the spin-disorder resistivity term ρ_{spd}. In the paramagnetic range, where the magnetic correlations are absent, electrons are scattered on entirely disordered magnetic moments. The spin-disorder resistivity originates in the exchange interactions acting on the conduction-electron spin and scales therefore with the De Gennes factor $(g-1)^2J(J+1)$ and with the square of the coupling parameter $\mathscr{J}$.[6] For a system with stable magnetic moments, ρ_{spd} is constant above the magnetic ordering temperature. In ferromagnets below T_C, ρ_{spd} decreases with temperature in a way characteristic for the type of magnetic excitation in a particular system. Finally, it should vanish in the low temperature limit. For low temperatures, a quadratic temperature dependence of ρ_{spd} can be derived[7,8] and is frequently observed experimentally.

The situation is less clear in antiferromagnets, in which the magnetic periodicity can be different from the crystallographic one. This leads to creation of new Brillouin zone boundaries (superzone boundaries) and, consequently, gaps can appear on the Fermi surface. In this case, the effective number of charge carriers is reduced leading to initial increase of the resistivity with decreasing temperature below the Néel temperature T_N.[9] Such effect can be found both in itinerant antiferromagnets[10] and in rare-earth local-moment systems.[9] The resistivity can be described as

$$\rho=\frac{\rho_0+\rho_{e\text{-}p}+\rho_{spd}}{1-gm(T)}, \tag{5}$$

where $m(T)$ is a normalized sublattice (staggered) magnetization. The truncation parameter g characterizes the effective reduction of the number of conduction electrons as a consequence of the Fermi level gapping. It is evident that this factor enhances the resistivity even in the low temperature limit. The difference between ρ_F (resistance in the ferromagnetic state) and ρ_{AF} (resistance in the antiferromagnetic state) depends on the width of the gap in the electron energy spectrum, which scales with the exchange coupling parameter $\mathscr{J}$. Therefore, the magnetoresistance effect connected with the metamagnetic transition (between the antiferromagnetic state and the state with "ferromagnetically" aligned magnetic moments) should scale approximately with ρ_{spd}, which is governed by similar parameters.

In compounds based on regular rare-earth metals, the ρ_{spd} values are, however, rather modest despite large ionic magnetic moments. The reason is apparently a weak coupling of the conduction electron spin and the ionic spin moment S. Much larger ρ_{spd} values can be expected in materials where a strong coupling can be expected. This situation is likely in actinide and transition metal intermetallic compounds, as will be demonstrated on several examples.

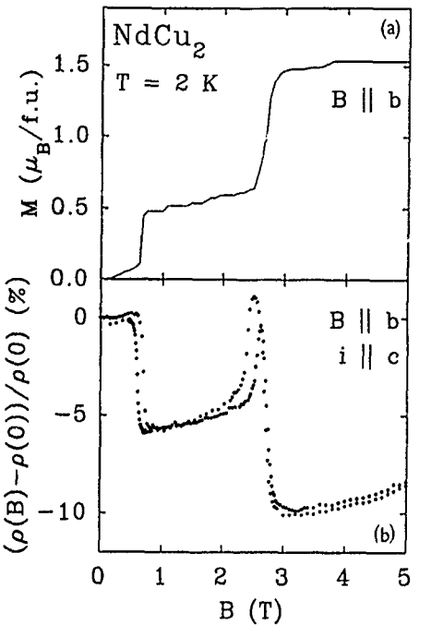

FIG. 1. (a) Magnetization and (b) transversal magnetoresistance vs magnetic field applied along the b axis measured on $NdCu_2$ single crystal at 2 K (data taken from Ref. 11).

III. EXAMPLES OF GMR IN BULK MATERIALS

As an example of one of the largest magnetoresistance effects in regular-rare-earth intermetallic compounds, we show in Fig. 1 the magnetoresistance of $NdCu_2$ which is antiferromagnetic below 6.3 K.[11,12] By applying the magnetic field along the b axis two metamagnetic transitions can be induced leading to a step-wise increase of the magnetization in $\cong$0.6 and $\cong$2.8 T. Both transitions are associated with pronounced changes of the resistance leading to $\Delta\rho/\rho \cong -10\%$ in 3 T. The increase of $\Delta\rho/\rho$ with the approaching critical field can be attributed to the enhanced scattering due to intersite fluctuations.[13,14]

The large magnetoresistance changes in $NdCu_2$ are confined to very low temperatures because of the low value of T_N. Therefore, $SmMn_2Ge_2$, which is antiferromagnetic between $\cong$100 and 150 K and ferromagnetic outside this range,[15,16] might be more attractive for applications. The transition from the antiferromagnetic state to a low-resistance ferro-state can be induced by moderate fields (below 1 T), but the reduction of the resistivity does not exceed 10%.

A similar situation can be found in $Ce(Fe_{1-x}Co_x)_2$, with ~10% cobalt substitution. This material first becomes ferromagnetic below ~180 K, and with further lowering temperature a transition to the low-temperature antiferromagnetic state appears at $\cong$80 K.[17,18] This transition manifests in a dramatic increase of the electrical resistivity.[19] The ferromagnetic (and presumably the low-resistance) state can be then recovered by application of a sufficient magnetic field.[19] Similar loss of ferromagnetism at low temperatures can also

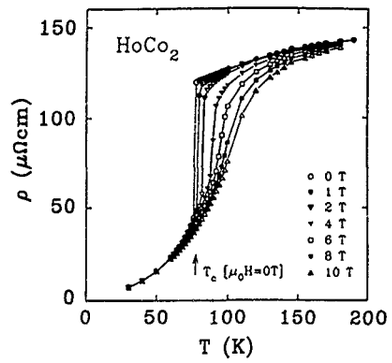

FIG. 2. Temperature dependence of the electrical resistivity in $HoCo_2$ in several magnetic fields (see Ref. 4).

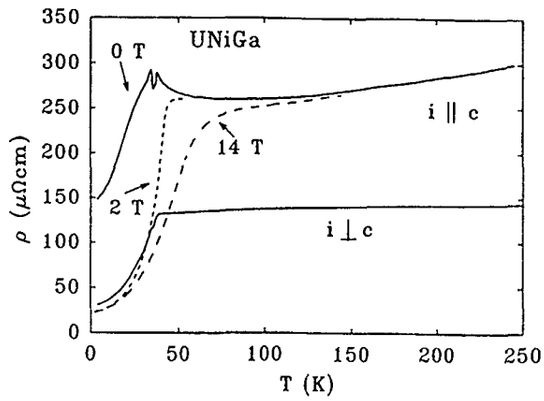

FIG. 3. Temperature dependence of the electrical resistivity in the UNiGa single crystal for $i \| c$ and $i \perp c$. For $i \| c$ also results measured in 2 and 14 T ($B \| c$) are displayed.

be observed for small substitutions of Fe (in $CeFe_2$) by Al,[20] Si,[21] Ru, Ir, and Os,[22] which could also lead to large magnetoresistance.

Significantly larger effects can be observed in materials, where the external magnetic field assists in the stabilization of magnetic moments. This situation can be followed, e.g., in RCo_2 compounds. For some rare earths, the Co moments are formed from the highly susceptible matrix of the $3d$ states by the concerted action of ordered rare earth moments at the Curie temperature T_C, which thus becomes a first order transition. Above T_C, the large resistivity is affected not only by disordered rare-earth moments, but the strong spin-fluctuations in the Co $3d$-electron subsystem contribute, as well. The electron-spin fluctuation scattering is removed in the transition by a sudden drop of a considerable absolute value (e.g., $\cong 80\ \mu\Omega$ cm in $DyCo_2$ and $HoCo_2$).[4,5,23] The effect of exchange fields of the $4f$ subsystem on the $3d$ one can be naturally assisted by the external magnetic field, which shifts the transition towards higher temperatures. Thus, for a particular temperature from a limited range above T_C, the resistivity can be reduced drastically. A typical example of $HoCo_2$ can be seen in Fig. 2. Qualitatively similar behavior also occurs in $DyCo_2$, $ErCo_2$, and $TmCo_2$.[4,5,23] Although present in compounds containing rare earths, the effect is clearly due to the onset of $3d$ magnetism in this case.

There are also purely d systems with a large magnetoresistance. One case known for many years is the equiatomic ordered FeRh compound.[24] It is antiferromagnetic below 340 K, where it undergoes a transition to the ferromagnetic state. At lower temperatures, the ferro-state can be achieved by the magnetic field, which increases from 0 T at 340 K to about 30 T at 4.2 K (the critical field is 4 T at room temperature). As the resistivity increases strongly at 340 K due to the $F \rightarrow AF$ transition, the suppression of antiferromagnetism in the field leads to a dramatic reduction of the resistivity. As the residual resistivity in the ferromagnetic state can be rather small, the relative drop of its value is largest—by the factor of 20—in the low temperature limit ($\Delta\rho \cong 20\ \mu\Omega$ cm). Recent calculations[25] yield the electron structure in both phases. The Fe atoms display local moments of $\cong 3\mu_B$, while the Rh local moments are zero in the antiferromagnetic configuration and $1\mu_B$ for the ferromagnetic configuration. This means that the Rh magnetic moment is induced by the $AF \rightarrow F$ transition similar to the onset of the Co magnetic moment at the ordering temperature in some RCo_2 compounds. Then both the spin-flip transition of Fe magnetic moments and the onset of Rh magnetism can be accounted for by the large magnetoresistance change in FeRh. Large magnetoresistance changes accompanying the magnetic-phase transitions in the transition metal sublattice have also been observed in the $La(Fe_xAl_{1-x})_{13}$ system.[26]

Much larger MR effects occur in systems with uranium, a most thoroughly studied light actinide. We will review some experimental data on UTX compounds, which are formed in several types of crystal structures. The compounds crystallizing in the hexagonal ZrNiAl structure have been studied most thoroughly. This structure consists of U-T and T-X basal-plane layers alternating along the c axis. The stronger U-U coupling within the plane leads to a very strong magnetic anisotropy confining the U moments in the c direction. The magnetic interactions along c are much weaker and in some cases antiferromagnetic with various propagation vectors. The electrical resistivity in antiferromagnetic compounds shows qualitatively different behavior for the current along the basal plane and along the c axis (see Fig. 3). A typical example is UNiGa,[27] which orders antiferromagnetically below 40 K. The ground state can be characterized by the sequence of $(++--+--)$ orientation of equal U magnetic moments of $1.4\mu_B$. The ferromagnetic configuration is reached in ~0.8–1 T (at 4.2 K). As shown in Fig. 4, the first-order metamagnetic transition is accompanied by a drastic decrease of the resistivity of about 120 $\mu\Omega$ cm ($\Delta\rho/\rho = 86\%$).[28] Knowing the complex magnetic phase diagram of UNiGa, one can gain some insight into the magnetoresistance effect by inspection of the $\rho(T)$ dependencies in various magnetic fields (Fig. 3). In high magnetic fields sufficient to suppress the antiferromagnetic correlations, $\rho(T)$ behaves as in a ferromagnet, with a resistance drop below the ordering temperature. Thus the anomalies in $\rho(T)$ found between 35 and 40 K, which are connected with several different antiferromagnetic phases existing in zero field, totally disappear in the field of 2 T. The slower increase of the resistivity in the ferromagnetic phase means that the largest

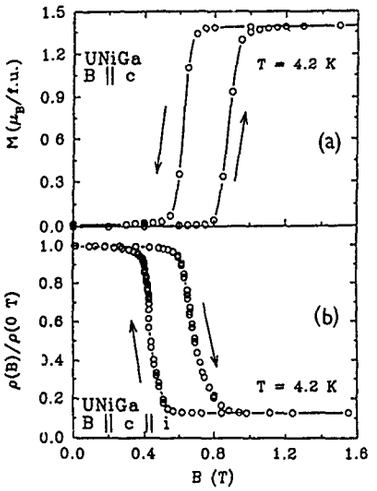

FIG. 4. (a) Magnetization and (b) relative electrical resistivity for $i \| c$ vs magnetic field applied along the c axis measured on UNiGa single crystal at 4.2 K.

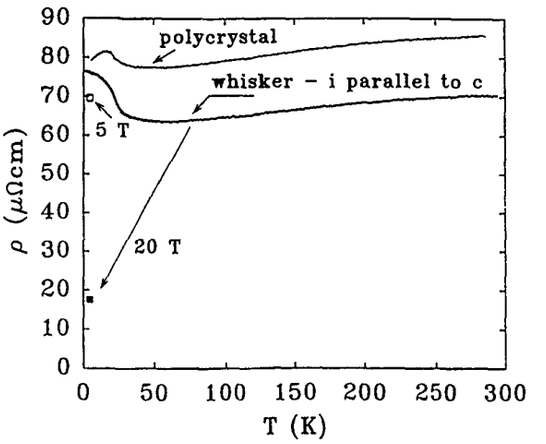

FIG. 6. Temperature dependence of the electrical resistivity of a UPdIn polycrystal and a single-crystalline whisker for $i \| c$ The two additional points indicate the value to which the resistance of the whisker drops in applied fields above the two metamagnetic transitions seen in Fig. 7.

drop $\Delta\rho \cong 200\ \mu\Omega$ cm is found at 25 K. Around this temperature a two-step metamagnetic process is observed (see Fig. 5). For current perpendicular to the c axis, which is sensing essentially the ferromagnetic ordering of U moments within the basal-plane sheets, the $\rho(T)$ dependence resembles that of a ferromagnet already in the zero-field phase, but the field applied along c still reduces the residual resistivity from ~30 to ~10 $\mu\Omega$ cm.

The second compound of this type of structure is UPdIn, where the layers of the U moments of $1.5\mu_B$ are stacked along c in the sequence $(++-+-)$, which gives a net ground-state magnetization of $1/5\mu_U$. As can be seen in Fig. 6, an increase of the resistivity is found at low temperatures for current along the c axis.[29] Below the inflection point in $\rho(T)$ at 20 K, which coincides with the ordering temperature, a gradual saturation to $\rho_0 \cong 80\ \mu\Omega$ cm is observed. For current perpendicular to the c axis, a more regular behavior with a low temperature decrease of the resistivity appears. In a field of 4 T along the c axis, the magnetic structure transforms into the $(++-)$ stacking, and the full parallel alignment of moments is achieved in 16 T. Both metamagnetic transitions (Fig. 8) are accompanied by a drop in the resistivity. The major part of the magnetoresistance effect (total drop of 60 $\mu\Omega$ cm) is concentrated into the latter transition. From these two examples with $\Delta\rho \gg \rho_0$, it is evident that the magnitude of $\Delta\rho/\rho$ at low temperatures is strongly dependent on the residual resistivity ρ_0 in a "ferromagnetic" state, which is essentially related to crystal imperfections. Inspecting the temperature dependence of $\Delta\rho/\rho$, we note that this parameter should decrease at high T even in cases where electron-phonon scattering is not of primary importance. The reason is the increase of the resistivity due to magnetic ex-

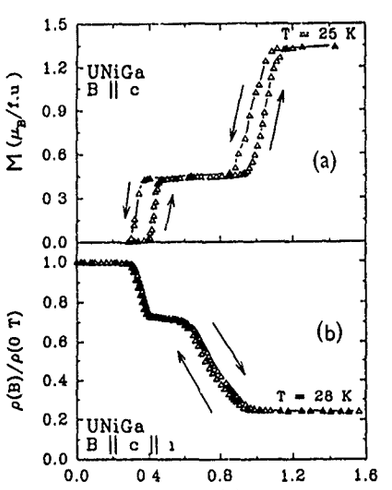

FIG. 5. (a) Magnetization and (b) relative electrical resistivity for $i \| c$ vs magnetic field applied along the c axis measured on UNiGa single crystal at 25 and 28 K, respectively.

citations, which affects $\rho(T)$ progressively with raising temperature up to the ordering temperature.

UNiGe[30] crystallizes in the orthorhombic TiNiSi structure type. Below 41.5 K, this compound orders antiferromagnetically with a propagation vector (0,1/2,1/2). Applying the magnetic field along the c axis, one first induces (in approximately 4 T) another magnetic structure with the propagation vector (0,1/3,1/3) and a net magnetic moment corresponding to the stacking $(++-)$. The parallel alignment of U moments is achieved above 10 T. In the longitudinal geometry $(i \| c, B \| c)$, we find that ρ is reduced by a similarly large relative value as in the compounds mentioned above (Fig. 8). The absolute value of the resistivity decrease is about 80 $\mu\Omega$ cm. However, in contrast to the previous cases, $\rho(B)$ first increases by the transition from the ground-state phase $(+-)$ to the one with the $(++-)$ stacking.

UPdGe[31] is formed within the same structure type. Unlike UNiGe, it is ferromagnetic below $T_C = 28$ K. The antiferromagnetic ordering (long wavelength modulated structure) existing between 28 and 50 K, can be suppressed by a moderate magnetic field applied along the c axis (see Fig. 9). The transition field can be tuned by temperature variations, and the maximum size of the drop of ρ can reach about 150 $\mu\Omega$ cm.

IV. DISCUSSION AND CONCLUSIONS

The examples presented above show unambiguously an additional contribution to the electrical resistivity due to the antiferromagnetic coupling of magnetic moments, which can be removed by forcing the moments to orient parallel to each other. This contribution does not vanish in the low-temperature limit, and at low temperatures it can contribute a substantial part of the total resistivity.

Concerning possible mechanisms by which the antiferromagnetic ordering influences the electrical resistivity, one should also consider the spin-dependent scattering, which can play an important role besides the Fermi-surface gapping, and which is often considered in the context of multilayers. In this concept the electrons with different spin orientation are supposed to experience different potentials and have a different k-space distribution. The origin of the spin-dependent scattering can be understood if we consider the different scattering amplitude for electrons with spin parallel or antiparallel to ionic magnetic moments in a local moment case. In band magnetism, the asymmetry of the scattering is given due to significantly different partial densities of states at E_F for each subband (spin-up or spin-down). In both cases, the increment of the resistivity in the AF state is dependent on a concentration of $+-$ interfaces. It is worth systematic experimental effort to check whether it is really the case, i.e., whether the larger resistivity in the AF state is due to an additional scattering mechanism, or if the explicit parameter is the modification of the effective conduction-electron concentration. In a case such as this there should be a proportionality between ρ_{AF} and ρ_F irrespectively of, e.g., the ρ_0 value. The unique proportionality constant given by the truncation factor mentioned above should be observed at least in the low-T, limit, where different excitations in antiferromagnetic and "ferromagnetic" states can be neglected. The size of the magnetoresistance effect should scale more with the size of the AF unit cell in this case.

Keeping in mind an applicability potential, future effort should focus on materials with exchange interactions strong enough to guarantee ordering in the room temperature range.

As shown in the example of FeRh, this need not lead to extremely high metamagnetic fields in compounds with competing ferro- and antiferro-interactions. The orientation on artificial multilayers or cluster systems is apparently not the only promising stream of GMR research.

A systematic comparison of magnetoresistance, Hall effect, thermal conductivity, and thermoelectric power has been made on systems exhibiting giant magnetoresistance (GMR), Co/Cu/Ni(Fe) multilayers, and AgCo granular alloys, for examples. Each property exhibits field dependence characteristic of the GMR and justifies its own merit in characterizing the conduction-electron scattering responsible for the GMR. The comparison was extended to intermetallic compounds such as $REGa_2$ and $RECo_2$ (RE: rare earth element) which also show a large magnetoresistance.

I. INTRODUCTION

The GMR in magnetic multilayers[1] is one of the most attractive subjects. Most of experimental works focus mainly on the magnetoresistance (MR).[2] To characterize the conduction electron scattering responsible for the GMR, it is best to study the Hall effect, thermoelectric power, and thermal conductivity simultaneously on the same sample and under the same experimental geometry.[3] From thermal conductivity measurements, it can be judged whether the scattering responsible for the GMR is large angle in nature or not. Such works on magnetic multilayers and granular alloys are still scarce.[4,5] Thermoelectric power measurements give information on the density of electron states at E_F. Thermoelectric power measurements on magnetic multilayers and granular alloys[6–8] reveal common main mechanism of conduction-electron scattering. The extraordinary part of the Hall resistivity contains information about the left-right asymmetry of conduction-electron scattering.[9] Several reports[10–13] correlate the anomalous behavior of the extraordinary Hall resistivity correlated with the GMR.

The large resistance change in UNiGa (Ref. 14) and $SmMn_2Ge_2$,[15] at their metamagnetic transition has a close similarity to multilayers. First of all, they have geometrical similarity, i.e., the neighboring magnetic layers are coupled antiferromagnetically at zero field, and are aligned ferromagnetically under magnetic fields.

We describe here the systematic comparison of the transport properties correlated with the GMR in both metallic superlattices and in magnetic granular films. For the multilayer, we chose a typical noncoupled one, Cu/Co/Cu/Ni(Fe), in which the large resistance state is attained utilizing the large difference of the coercive field of the two ferromagnetic components. AgCo was selected as an example of granular alloys with the largest MR ratio We further extend the comparison to the with $REGa_2$ and $RECo_2$.

II. EXPERIMENT

The multilayer samples are Cr(30 Å)/[Co(20 Å)/Cu(40 Å)/Ni(Fe)(20 Å)/Cu(40 Å)]$_{50}$ (sample ML-1) and Cr(30 Å)/[Co(20 Å)/Cu(40 Å)/Co(1 Å)/Ni(Fe)(20 Å)/Co(1 Å)/Cu(40 Å)]$_{50}$ (sample ML-2). AgCo granular samples containing two different Co concentrations of 27.2 at. % (GL-1) and 42 at. % (GL-2) have a total thickness of 5000 Å. Both systems were evaporated in ultrahigh vacuum on glass substrates at room temperature. Samples for the Hall effect and the MR were made with a mask suitable for transport measurements. Samples for thermal measurements were evaporated on thin glass substrates (~80 μm) in order to reduce the thermal shunt effect. $REGa_2$ (RE:Nd, Pr, and Sm) single crystals were grown in a triarc furnace by the Czochralski pulling method. Polycrystalline $RECo_2$ (RE: Ho and Dy) were melted in an arc furnace from elements with a purity of at least 99.9%, and were annealed 100 h at 900 °C.

III. RESULTS AND DISCUSSION

A. Magnetic multilayers and granular alloys

The larger MR ratio is desirable for investigating the influence of the GMR effect on other transport properties. The MR ratios at 4.2 K for ML-1 and GL-1 (annealed at 240 °C) are 51% and 84% for the field in-plane, respectively. The MR ratio is defined as $MRR_s=(\rho_{max}-\rho_s)/\rho_s$ (ρ_{max} and ρ_s are a maximum value of the electrical resistivity ρ and ρ at maximum applied field, respectively).

The result of the field dependence of the thermoelectric power (S) for ML-2 is shown in Fig. 1 along with the corresponding MR curves. The resemblance of the field dependence to that of MR is clear, including the anisotropy, which suggests that the conduction-electron scattering responsible for GMR plays a major role also in the $S(H)$ dependence. In the spin-split density of states (DOS) model given by Shi *et al.*,[16] S is a linear function of $\rho(0)/\rho(H)$. which was reported to hold well for Co/Cu multilayers and for AgCo granular alloys.[16,17] The corresponding plot for ML-2 is

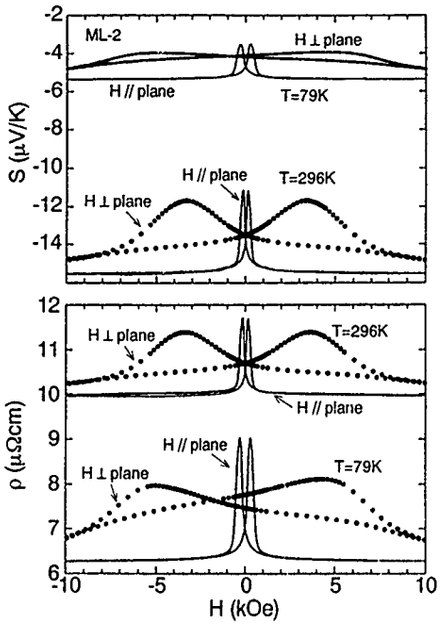

FIG. 1. The field dependence of the thermoelectric power (S) and the resistivity (ρ) in ML-2 for the fields parallel and perpendicular to the film.

shown in Fig. 2. The data points are also on a line regardless of the field direction. Recently, Tsui *et al.* reported a more restricted scaling relation of S, i.e., the plots of $S(H)/T$ vs $\rho(0)/\rho(H)$ for $T=78$, 113, and 161 K in Co/Cu superlattices are all on a single line. For the present multilayers, however, the data plotted in the same procedure at 79 and at 296 K are on different lines, which indicates that the scaling relationship by Tsui *et al.* is not a universal one for GMR systems.

Thermoelectric power measurements on AgCo granular alloys were reported by Piraux *et al.*[5] and Shi *et al.*[16] The dependence $S(T)$ in the two works is roughly similar; however, two different characteristics have been found at lower temperatures. Shi *et al.*[16] reported that S changes sign from negative at high temperatures to positive below about 25 K. In Ref. 5, on the other hand, the sign is always negative and a small negative peak near 70 K was found. We also measured S vs T on an as-grown sample and on one annealed at

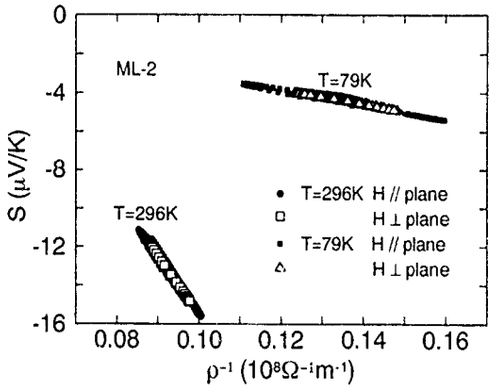

FIG 2. $S(H)$ vs $1/\rho(H)$ plots for ML-2 obtained from the data in Fig. 1

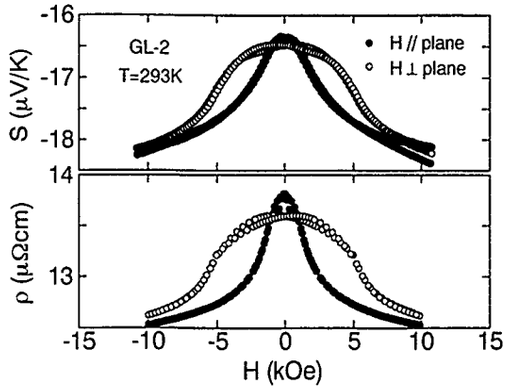

FIG. 3. The field dependence of S and ρ of GL-2 for the fields parallel and perpendicular to the film.

310 °C (not shown). Overall, our result is similar to that in Ref. 5, although we have found neither the sign change nor the negative minimum. The sign change might not be intrinsic in AgCo granular samples since it has not been found in either the present work or in Ref. 5. The anisotropy observed in the MR is also clearly reflected in the $S(H)$ dependence as shown in Fig. 3. The figure shows that the scattering responsible for GMR dominates also in the $S(H)$ dependence in AgCo granular alloys although there is a slight discrepancy for the H//plane curve due to the thermal delay effect.

We have reported the field dependent thermal conductivity correlated with GMR for the first time on Co/Cu/Ni(Fe)/Cu multilayers.[4] Piraux *et al.* reported the extensive investigation of thermal conductivity on Co 20 vol % (27.2 at. %) AgCo granular alloys.[5] In order to measure the absolute value of thermal conductivity, their method of using very thick and substrate free films has a considerable advantage. However, we can obtain data as reliable as them even on a thinner sample with a substrate for the field dependent part of thermal conductivity $\Delta\kappa(H)$ as[4]

$$\Delta\kappa(H)=K_{TS}(l/S)DT(H)/\Delta T_S, \tag{1}$$

where K_{TS} is the total thermal conductance of a sample including the substrate at saturation field, l the sample length, and S the sample cross section; $DT(H)/\Delta T_S$ is the ratio of the field dependent change of the temperature gradient to that at saturation field. Figure 4 shows typical examples of the field dependent part of thermal conductivity $\Delta\kappa(H)$ for ML-1 and GL-1 along with the calculated $\kappa(H)$ from the field dependence of $\rho(H)$ measured on the same samples based on the Wiedemann–Franz law (W-F-L),

$$\kappa(H)=L_0T/\rho(H), \tag{2}$$

assuming the Lorenz number of $L_0=2.45\times10^{-8}$ W Ω/K^2. Present experiments show that the W-F-L is well obeyed at least for the field dependent part of thermal conductivity both for the multilayer and for the granular samples within a 5% accuracy. It agrees with the result of Piraux *et al.* where the absolute value of thermal conductivity on the granular AgCo samples fulfills the W-F-L within a 10% accuracy. These results suggest that the conduction-electron scattering re-

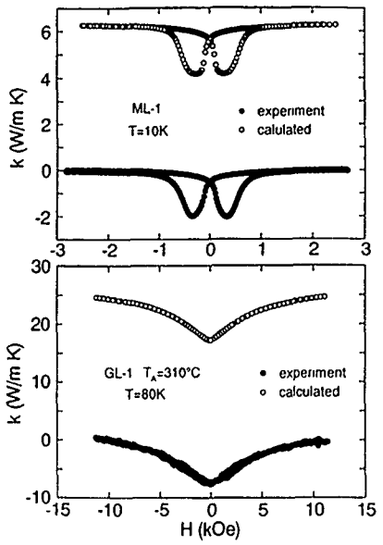

FIG. 4. The field dependence of the thermal conductivity. The calculated curves from $\rho(H)$ based on the W-F-L are also given for comparison.

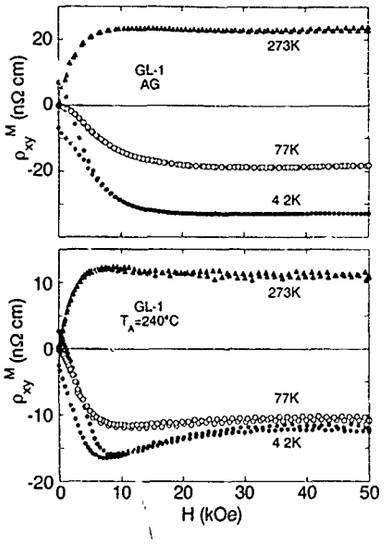

FIG. 5. The $\rho_{xy}(H)$ dependence for GL-1

sponsible for GMR in AgCo granular alloys is large angle in nature as well as in the magnetic multilayers.

The Hall effect in magnetic multilayers and granular alloys is still controversial.[11–13] The key issue is the field dependence of R_S, which has not been taken into account by most researchers.[11,13] The Hall resistivity ρ_{xy} is described as the sum of the two terms, the normal part proportional to magnetic field H and the extraordinary one ρ_{xy}^M proportional to magnetization M as

$$\rho_{xy}=R_0H+4\pi R_SM, \tag{3}$$

where R_0 and R_S are the normal and the extraordinary Hall coefficient,[9] respectively. In most experiments on ordinary ferromagnetic films and on multilayer samples[9,12] with a small MR ratio, $\rho_{xy}(H)$ has been described fairly well by Eq. (3), assuming a field independent R_S. In this case $\rho_{xy}(H)$ is a simple superposition of a linear normal part and an anomalous term that mimics the $M(H)$ dependence. During recent experiments on magnetic multilayers exhibiting the GMR, Fe/Cr,[10,12] and Co/Cu (Ref. 18) multilayers, an anomalous peak in the field dependence of $\rho_{xy}(H)$ has been found. It can never be explained by a field independent R_S since M increases monotonously with increasing field. This suggests that R_S, representing the magnitude of asymmetric scattering of conduction electrons, is no longer a field-independent constant in GMR systems. R_S is known to originate from two different asymmetric scattering mechanisms, i.e., the skew scattering and the side-jump mechanisms.[9]

$$R_S=a\rho+b\rho^2, \tag{4}$$

where a and b represent the magnitudes of the skew-scattering and the side-jump components, respectively. Taking into account the $\rho(H)$ dependence, Eq. (3) has been successfully applied to reproduce the anomalous $\rho_{xy}(H)$ dependence. For both Fe/Cr (Ref. 12) and Co/Cu (Ref. 18) multilayers, the experimental data R_S/ρ vs ρ are nearly on a line, which means that the parameters a and b are independent of magnetic field strength. In other words, the scattering responsible for the GMR has the same characteristics as that of the residual scattering at saturation fields from the viewpoint of left-right asymmetry.

We cannot properly explain the Hall effect on large GMR samples without taking into account the field dependent decrease of conduction-electron scattering. Granular systems cannot be a exception. For AgCo granular samples at 4.2 K, Xiong *et al.*[11] reported an experimental correlation $\rho_{xy}\propto\rho^{3.7}$ conflicting with the existing theory given by Eq. (3) without taking into account the field dependence of ρ. In order to clarify the origin of the discrepancy, we carefully measured the field dependence of ρ_{xy} simultaneously with MR. M was also measured in the same geometry, i.e., the $H\perp$ film plane. Figure 5 shows the $\rho_{xy}(H)$ dependence on an as-grown sample (denoted as AG) and a sample annealed at 240 °C (T_A=240 °C) for 15 min, where R_0 was already subtracted using the linear slope at higher fields. It is negative at 4.2 K and the overall behavior is basically the same as that of Xiong *et al.*[11] The field dependence for the as-grown sample resembles that of M in Ref. 11, including the hysteresis. ρ_{xy}^M shifts to a positive direction with increasing temperature, and the sign is always positive at 273 K.

The most salient feature is the peak below 10 kOe for T_A=240 °C. The dependence is close to that reported for Fe/Cr (Ref. 12) and Co/Cu (Ref. 18) multilayers exhibiting the large GMR. Xiong *et al.*[11] asserted the independence of R_S on H based on the fact that the field dependence of ρ_{xy}^M resembles that of M. However, the resemblance exists only on heat treated samples at low temperatures. Even for these samples, the resemblance is only approximate (see Fig. 6). For the samples annealed at higher temperatures in the both experiments, however, ρ_{xy}^M shows a peak or more complex structures below 1 T. If Fig. 1 in Ref. 11, T_A=330 °C, for example, is re-examined carefully, one can clearly identify a peak of similar magnitude to our data, i.e., the magnitude of the peak is about 150% of the saturation value of ρ_{xy}^M if the

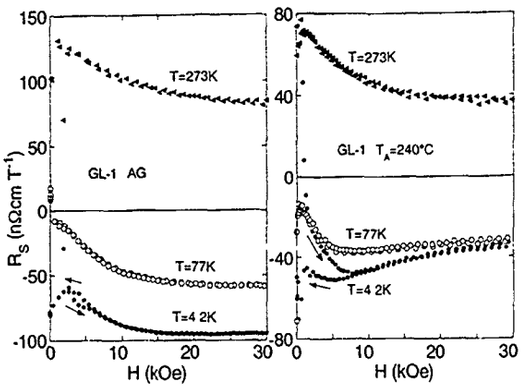

FIG. 6. The $R_S(H)$ dependence for GL-1 calculated from $\rho_{xy}^M(H)$ and $M(H)$ measured in the same geometry.

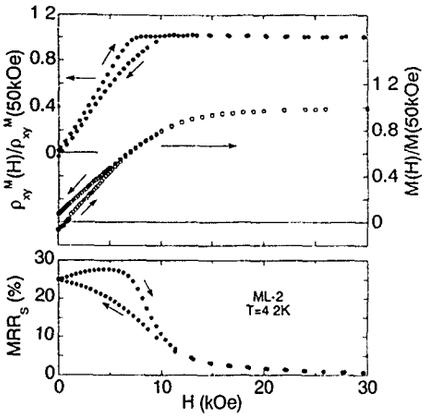

FIG. 7. The field dependence of the normalized Hall resistivity, M, and MR for ML-2 in the same geometry

normal part were properly subtracted. It must be pointed out that one must determine the extraordinary part of Hall resistivity (not the total Hall resistivity) within the required precision in order to discuss the influence of the GMR effect on the left-right asymmetry of conduction-electron scattering.

Starting from Eq. (3), the peak in ρ_{xy}^M indicates that R_S decreases with increasing H since M increases monotonously. Due to the competition between the increasing M and the decreasing R_S, a peak may appear in the field dependence of ρ_{xy}^M. It seems very natural since the magnitudes of the two terms in Eq. (4) decrease with increasing H for constants a and b. Of course, there is no guarantee that a and b are constant since the character of conduction-electron scattering might change with field and temperature. In order to see the field dependence more clearly, $R_S(H)=\rho_{xy}^M(H)/[4\pi M(H)]$ is plotted against H in Fig. 6. The dependence of R_S on H is far beyond the experimental error. The field dependence at 273 K is relatively simple since the predominant side-jump component with positive sign decreases monotonously with increasing H in the same manner as the MR. The dependence is not simple at lower temperatures since both the negative skew-scattering and the positive side-jump one compete. At low fields, R_S initially decreases with H since the decrease of the positive side-jump component with ρ^2 dependence overcomes the increase of the negative skew-scattering component with ρ dependence. R_S has a peak at a field where the change of the two components becomes equal. Additional details of the AgCo system will be published elsewhere.[19]

In the noncoupled multilayers, ρ_{xy}^M looks different, as shown in Fig. 7. No peak can be seen against H; however, it does not mean that R_S is independent on ρ. If R_S is constant, the field dependence of ρ_{xy}^M and M must be exactly alike. However, ρ_{xy}^M becomes nearly constant above 10 kOe while M is still increasing. Above 10 kOe, the increasing contribution to the second term in Eq. (3) from M is canceled out by the decreasing R_S correlated to the negative MR in Fig. 7. The hysteresis is also largely different between ρ_{xy}^M and M: i.e., we find the largest difference between the increasing and the decreasing field curves near zero field for M while it is near 7 kOe for ρ_{xy}^M. That can be also understood as due to the field dependence of R_S since the largest difference in the MR ratio is near 7 kOe as is also shown in Fig. 7. It must also be noted that the arrows given to the hysteresis curves for ρ_{xy}^M and M are directed inversely. The present Hall effect measurement proves that the reduction of conduction-electron scattering associated with the GMR undoubtedly affects the field dependence of the extraordinary Hall resistivity both in the magnetic multilayers and in granular alloys. Furthermore, it gives a clue that some change in the scattering character with field strength (the field dependence of a and b) is larger in granular alloys compared to ordinary multilayers such as Fe/Cr (Ref. 12) and Co/Cu.[18]

B. Intermetallic compounds

In rare earth intermetallic compounds, the large MR effect associated with metamagnetic transitions is not exceptional. We first list the characteristics to compare to the magnetic multilayers and granular alloys.

(1) The effect has a magnetic origin.

(2) The MR ratio is larger than 10% with negative sign.

(3) The dimensionality of magnetic layers plays an important role.

(4) Different conduction electron mean free paths of two spin-split bands play an essential role.

(5) The magnitude of each magnetic moment does not change under the magnetic field.

Of these, (1) and (2) are taken as necessary conditions as the starting point. Both the UNiGa (Ref. 14) and $SmMn_2Ge_2$ (Ref. 15) have the characteristic (3), which is not a necessary condition for granular alloys but is for the multilayer samples. Characteristics (4) and (5) seem to be key issues to the usual GMR effect.

Recently many RE- or U-intermetallic compounds have been investigated and few compounds have been found to possess the above characteristics except for characteristic (4). An example is $NdGa_2$, although the definite magnetic structure is not clear yet.[20] For most RE, $REGa_2$ has an antiferromagnetic ground state and shows several step metamagnetic transition. $PrGa_2$ shows two peaks in the MR near the spin-flip transition as was already reported for $ErGa_2$ (Ref. 21),

while $SmGa_2$ shows a steplike increase of MR at each metamagnetic transition.[22] The field dependence of the MR for $NdGa_2$, which resembles that of UNiGa, is shown in Fig. 8 along with M and ρ_{xy} at 4.2 K. Clear resistivity drops can be seen associated with metamagnetic transitions. $NdGa_2$, we do not discuss in depth here, but it can be stressed that a large negative MR over 40% is obtainable on a compound without the characteristics of (4).

YCo_2 exhibits a typical itinerant metamagnetism at high magnetic fields.[23,24] When Y is replaced by magnetic RE ions, the exchange field from the ions splits the d band and a ferrimagnetic state is stabilized below T_C. The transition is of the first order for Er, Ho, and Dy with a large and sudden change of resistivity.[25] Recently $HoCo_2$ and $ErCo_2$ have been reported to show a drastic resistivity decrease under magnetic fields above T_C.[26] The decrease may be caused by the suppression of spin-fluctuation scattering due to the field-induced transition.

This system has no characteristic (3) but has (4), on the same level as magnetic multilayers and granular alloys. The temperature dependence of the Hall coefficient, the resistivity, and the magnetic susceptibility are shown in Fig. 9 for $HoCo_2$ and $DyCo_2$. Overall, $\rho(T)$ is close to those reported by Gratz *et al.*[25] R_H is always positive for $HoCo_2$ while for $DyCo_2$ it changes sign depending on T, which suggests that the two components in Eq. (4) have a different sign in $DyCo_2$.

Figure 10 shows the field dependence of MR, ρ_{xy}, and M in the same geometry. The magnitude of the transverse MR in polycrystalline $HoCo_2$ is nearly the same as was reported for the longitudinal MR in the single crystal. For $DyCo_2$, a MR ratio over 25% has been observed at 138 K, despite the fact that the large spin-fluctuation scattering already exists below T_C and the sample quality is not satisfactory. The main source of the resistance drop may be the suppression of spin-fluctuation scattering due to field-induced band splitting.[26]

From the band structure calculation on YCo_2,[23,24] on the other hand, we naturally expect that the s-d scattering contribution similar to the usual GMR effect in the magnetic multilayer also plays a role. In a paramagnetic state, the valence band structure of $HoCo_2$ and $DyCo_2$ is similar to YCo_2. Under that condition, the s-d Mott mechanism may reduce the mean free path of s-like conduction electrons since the Fermi level is just at the dropping part of the d band where the density of the d-like states is still high, close to the Stoner criterion.[23,24] In a field induced ferrimagnetic state, the majority d band is put under the Fermi level, as was previously determined for a ferromagnetic YCo_2.[23] The mean free path of s electrons becomes longer compared to that of a paramagnetic state due to the disappearance of the s-d scattering in the majority band. As a result, the total resistivity decreases at the field-induced transition to the ferrimagnetic state. This mechanism resembles that responsible for the GMR effect in magnetic multilayers.[3] Starting from the low resistivity ferromagnetic (ferrimagnetic) state, the difference between the two systems is how the mean free path of conduction electrons is suppressed in the low filed high resistive state. For the state in magnetic multilayers the

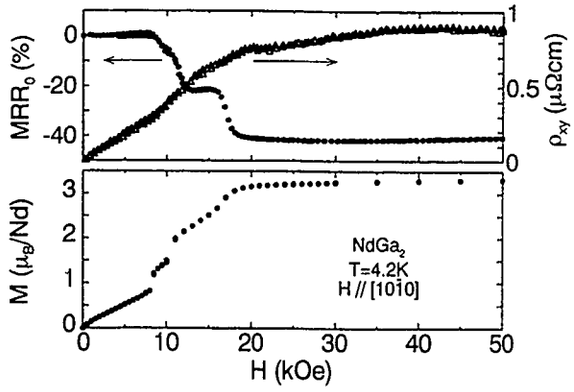

FIG. 8. The field dependence of the MR ratio, ρ_{xy}^M, and M for $NdGa_2$.

suppression is made by the averaging the conduction electron mean free path in the two spin bands over successive magnetic layers with the reverse magnetic moment, while for the paramagnetic state in $RECo_2$, the mean free paths in the both spin bands are suppressed by the s-d Mott mechanism which disappears for the majority band in the field-induced ferrimagnetic state. In other words, the s-d scattering averaged over more than two ferromagnetic layers in antiferromagnetically aligned multilayers is, in effect, similar to that in the paramagnetic state with a high d-electron density of states at E_F. Of course, for the $RECo_2$ system, band splitting apparently reduces the spin-fluctuation scattering which may be the main mechanism of the resistance drop in this system. However, we cannot ignore the possible contribution of the s-d mechanism to the MR at this stage.

For both compounds, the field dependence of ρ_{xy} resembles that of M below T_C. Above T_C, the field dependence is clearly different from that in ordinary ferromagnetic films. ρ_{xy} shows a clear decrease at higher fields, especially at 90 K for $HoCo_2$ and at 138 K for $DyCo_2$, whereas M is still increasing in the same fields. The decrease cannot be

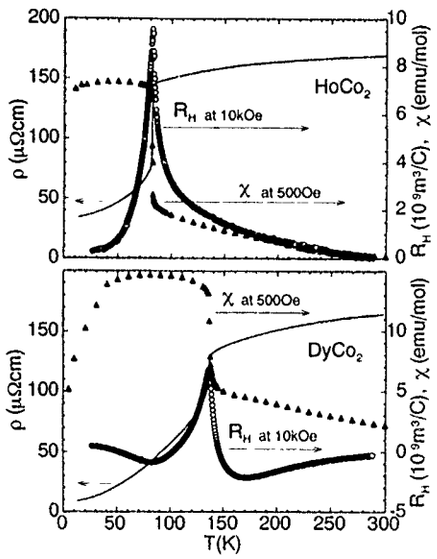

FIG. 9. The temperature dependence of ρ, R_H, and χ for $HoCo_2$ and $DyCo_2$.

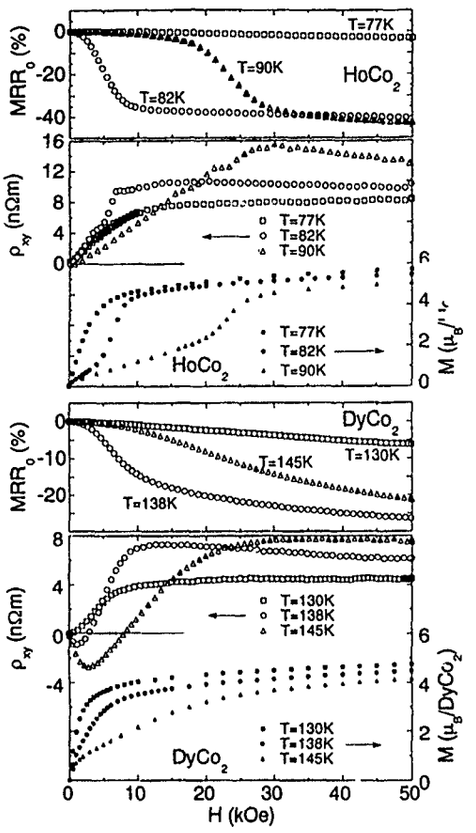

FIG. 10. The field dependence of the MR ratio, ρ_{xy}, and M for $HoCo_2$ and $DyCo_2$. The measurements were done for the increasing field direction.

due to the normal part of ρ_{xy} since ρ_{xy} in the ferrimagnetic state is nearly constant at high fields. The source of the decrease may be the same as that in the magnetic multilayers and granular alloys, i.e., reduction of left-right asymmetric scattering associated with negative MR. At lower fields, ρ_{xy} deviates to positive for $HoCo_2$ and to negative for $DyCo_2$ compared to the field dependence expected from the magnetization curves. For $DyCo_2$, ρ_{xy} even changes its sign. This can be understood if we take into account the field-induced transition from para- to ferrimagnetic states. The side-jump component in Eq. (4) is effective only in the ferromagnetic or ferrimagnetic state whereas the skew-scattering component also contributes in paramagnetic state. For $HoCo_2$ both components are positive while for $DyCo_2$ the skew component is negative and the side-jump one is positive, which was already shown in Fig. 9. In the low field paramagnetic range, the skew term dominates the whole sign.

Compared to magnetic multilayers and granular alloys, the Hall resistivity in $RECo_2$ system shows both a similarity and a difference. The decrease at higher fields correlated to the decreasing resistivity is the similarity while the strange dependence at lower fields is the later and probably related to characteristic (5) described earlier.

To summarize: (1) The effects correlated to the GMR appeared in all the transport properties and for all the materials investigated. (2) Simultaneous measurements of the different transport properties revealed both a difference and a similarity in the character of conduction electron scattering. (3) The existence of neither itinerant magnetic electrons nor two dimensional ferromagnetic layers is a necessary condition for the GMR effect in intermetallic compounds.

A large intrinsic magnetoresistance has been found near the ferromagnetic transition of metallic manganese oxides with perovskite-type crystal structure. The magnetic and transport properties were measured on bulk and thin-film $La_{1-x}A_xMnO_{3+\delta}$ with A=Ca,Sr,Ba. Assuming the double-exchange model proposed by Zener [Phys. Rev. **81**, 440 (1951); **82**, 403 (1951)], the strong dependence of the transport properties on the magnetic field and also on the chemical composition is attributed to the mixed Mn^{3+}/Mn^{4+} valence.

I. INTRODUCTION

Much interest has been focused on giant magnetoresistance (GMR) since the first observation of it in metallic multilayers consisting of ferromagnetic layers which are separated by nonmagnetic spacer layers.[1] Meanwhile, resistance changes $\Delta R/R(H=0)$ of up to 60% at 10 K,[2] or 40% at room temperature,[3] have been reported. Beside multilayers, the effect has also been found in heterogeneous alloys with superparamagnetic precipitates embedded in a nonmagnetic metallic matrix. Spin-dependent scattering near the interface between the ferromagnetic and the nonmagnetic phase is the physical origin of the magnetoresistance in these systems, whereas the "conventional" anisotropic magnetoresistance (MR) of ferromagnets and also the isotropic MR which is attributed to magnetic impurity scattering are intrinsic properties of the material.

Although today's interest in GMR mainly focuses on the heterogeneous systems with ferromagnetic/nonmagnetic interfaces, one has to keep in mind the very high intrinsic MR of some materials, which is possible if the electronic transport is strongly related to the spin order, especially in those cases of coincidence of a magnetic and a metal-semiconductor transition. Such an intrinsic GMR has, e.g., been reported for some ferromagnetic Eu-chalcogenide alloys (T_C=6 K). In the ferromagnetic region, the resistance could be lowered by more than four orders of magnitude by applying a magnetic field of less than 1 T.[4] It has been shown by several authors (e.g., Refs. 5–7), that the intrinsic GMR is not restricted to low temperatures if a system with a suitable high transition temperature is chosen. One example is the mixed-valence perovskite-type $La_{2/3}Ba_{1/3}MnO_{3+\delta}$, for which we found a lowering of the resistance of $\Delta R/R(H=0)>60\%$ at room temperature.[7] Leaving out for a moment the very high magnetic field of 7 T which is necessary, these numbers are still higher than those reported for multilayer systems.

In this article we first review magnetic properties of Mn-oxides with distorted perovskite-type structure. Then the effect of spin disorder on the transport properties is discussed. In Sec. IV also some results on "doped" bulk samples are reviewed, where chemical impurities have been introduced by partially substituting Cu for Mn.[8] The effect of an external field on the resistance is then reported in Sec. V for various thin-film samples, and we will finally conclude with a short summary.

II. EXPERIMENTS

The bulk samples were prepared by standard ceramic techniques from oxides, carbonates, or acetates either from an acid solution as described earlier[9] or just by repeated grinding and annealing in air, which finally resulted in black, compact sintered pellets. Using some of these samples as laser targets, thin films with thicknesses between 100 and 500 nm were grown on $SrTiO_3$ 10×10 mm^2 substrates in (100) and (110) orientation by laser deposition as described elsewhere.[10] The substrate temperature had to have a temperature range around T_S=600 °C to obtain epitaxial growth. The sample quality was controlled by x-ray diffraction and also by reflection high-energy electron-diffraction (RHEED) measurements. A higher substrate temperature resulted in polycrystalline films, which did not differ in their electric properties from the epitaxial ones. Since we did not carry out chemical analysis, the exact oxygen content of our samples is uncertain and thus we assume an oxygen excess δ.

III. MAGNETIC Mn-OXIDES WITH PERVOSKITE STRUCTURE

Early investigations on magnetic oxides with distorted perovskite-type structure[11] showed that antiferromagnetic, insulating $LaMnO_3$ can be driven into the metallic state by replacing a certain amount of the trivalent La by divalent Ca, Sr, or Ba. At the same time as electric transport becomes possible, the antiferromagnetic spin order changes via a canted spin structure or an antiferromagnetic spiral arrangement into a ferromagnetic state. The crystal symmetry changes from tetragonal, monoclinic, or rhombohedral toward cubic symmetry. The electric and magnetic properties are also very sensitive on the preparation parameters, which

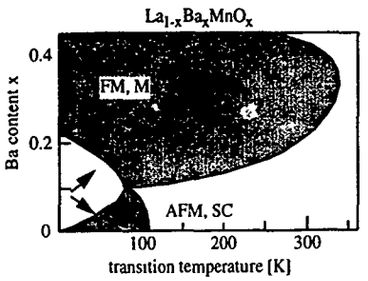

FIG. 1. Schematic phase diagram of $La_{1-x}Ba_xMnO_3$. Antiferromagnetic (AFM), semiconducting (SC) $LaMnO_3$ becomes ferromagnetic (FM) and metallic (M) if trivalent La is substituted by divalent Ba. Similar phase diagrams can be drawn for Sr and Ca substitution (Ref. 11).

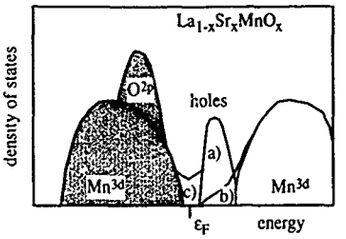

FIG. 2. Schematic diagram of the band structure of $La_{1-x}Sr_xMnO_{3+\delta}$ (Ref. 19). The initial bandgap of about 1.3 eV is reduced by the hole states (a) due to Sr doping and (b) due to excess oxygen. (c) States at ϵ_F are probably introduced by band broadening in the ferromagnetic region for high Sr content $x>0.15$ (Ref. 20).

is mainly the annealing temperature.[7,11–13] A schematic magnetic phase diagram for $La_{1-x}Ba_xMnO_3$ is shown in Fig. 1.

The antiferromagnetic coupling between Mn^{3+} ions in the undoped parent compound $LaMnO_3$ is believed to be transferred by superexchange via the intermediate oxygen, leading to a layered spin structure with antiferromagnetic coupling between adjacent layers and ferromagnetic order within the layers.[14] Weak (or parasitic) ferromagnetism is observed even in the undoped compound and is interpreted as an intrinsic property[15] or to result from an excess of oxygen δ.[11]

Zener was the first to develop the mechanism of double exchange to understand the occurrence of ferromagnetism together with metallic conductivity, if a portion of the La is substituted by a divalent metal.[16] A corresponding number of formerly triply charged Mn must then become quadruply charged, and the displacement of these holes increases the conductivity and at the same time provides a mechanism for ferromagnetic interaction. The double-exchange model proceeds from a resonance valence-bond description of the Mn $3d$ electrons and O $2p$ electrons. While no electron transfer is possible from a Mn^{3+} to another Mn^{3+} ion, this changes by introducing some Mn^{4+} ions, and in this case the bond between Mn ions of different oxidation state can be described as a resonance hybrid between the two states,

$$\Psi_1: \ Mn^{3+}O^{2-}Mn^{4+}, \quad \Psi_2: \ Mn^{4+}O^{2-}Mn^{3+}.$$

A fluctuation of the electron is energetically favored and, as it has been shown for such a simplified physical model,[17,18] the transfer integral for one electron becomes

$$t_{ij}=b_{ij}\cos(\theta_{ij}/2),$$

with some constant b_{ij}, when θ_{ij} is the angle between the two ionic spins. This dependence of the carrier energy on θ_{ij} is, together with the competing antiferromagnetic superexchange interaction, the reason for either a canted spin arrangement with two sublattices in the ferromagnetic region, or a spiral arrangement, which is stable in a certain range of the dopant concentration x.

IV. MAGNETIC AND CHEMICAL DISORDER

While all of the Zener carriers participate in double exchange, at least at low concentrations x, only a small fraction of them is involved in the conduction process.[18] This peculiarity of the conduction band was recently confirmed in a spectroscopic investigation by Chainani, Mathew, and Sarma:[19] Their x-ray photoelectron spectroscopy (XPS) and ultraviolet photoemission spectroscopy (UPS) spectra of sintered $La_{1-x}Sr_xMnO_3$ showed only a negligible intensity at the Fermi level even in the metallic region $x>0.2$, and thus the authors conclude that the energy gap (or a pseudogap with a low density of states) of the "pure" semiconducting compound $LaMnO_3$ survives even if chemical holes are doped by introducing Sr. Figure 2 shows the schematic band structure as suggested by these authors. A theoretical study of $La_{1-x}Sr_xMnO_3$, which extends the double-exchange model by including band-structure effects, predicts a band broadening at the ferromagnetic transition, which reduces the gap or even closes it, thus leading to increased or metallic conductivity in the ferromagnetic region[20] and activated conductivity above T_C. This might explain the activated behavior we observed above T_C also in the metallic ferromagnets (Figs. 3 and 4).

As a consequence of this interplay between spin order and the small number of mobile charge carriers, the conduc-

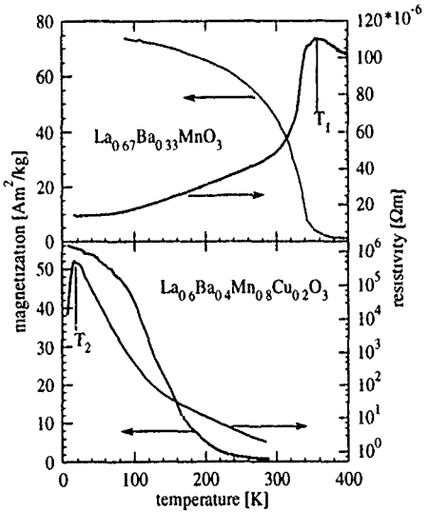

FIG. 3. Magnetization (under an applied field of $\mu_0 H=0.4$ T) and resistance vs temperature of sintered $La_{0.67}Ba_{0.33}MnO_3$ [upper figure (a)] and $La_{0.6}Ba_{0.4}Mn_{0.8}Cu_{0.2}O_{3+\delta}$ [lower figure (b)]. Data taken from Ref 8.

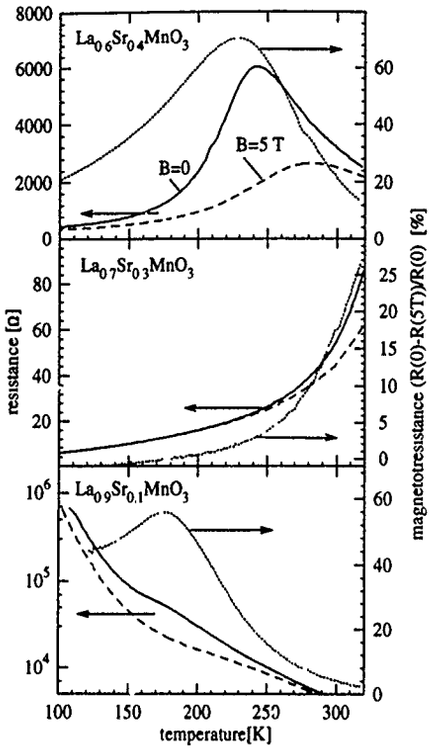

FIG. 4. Temperature dependence of the resistivity at zero field (solid line, left-hand-side axis) and under an applied field of $\mu_0 H = 5$ T (dashed) for thin films of $La_{0.9}Sr_{0.1}MnO_{3+\delta}$ $La_{0.8}Sr_{0.3}MnO_{3+\delta}$ and $La_{0.6}Sr_{0.4}MnO_{3+\delta}$. The dotted curves (right-hand-side axis) represent the relative MR effect MR $=[R(0T)-R(5T)]/R(0T)$.

tivity is strongly affected by perturbations of the spin lattice. This leads in some cases even to an Anderson type of localization and, therefore, semiconducting behavior.[21] Figure 3(a) shows the temperature dependence of the magnetic moment and the resistance of the metallic ferromagnet $La_{0.67}Ba_{0.33}MnO_3$. At low temperature $T \ll T_C$, metallic behavior is observed, i.e., a positive temperature coefficient of resistivity, $\rho^{-1} d\rho/dT > 0$, down to the lowest temperature of 4.2 K. Near T_C, a very prominent spin-disorder scattering leads to a strong increase of resistivity. The resistance reaches a maximum at $T_1 \approx 355$ K, and then decreases, i.e., activated behavior is observed above the ferromagnetic transition.

If 20% of the Mn is replaced by Cu, we obtain the curves of Fig. 3(b). Beside the lowered T_C, the saturation magnetization differs significantly from the calculated spin-only values of the $3d$ elements, thus indicating a global or local canting of spins. The resistivity is increased by several orders of magnitude, compared to Fig. 3(a), and exhibits activated behavior also in the ferromagnetic region. The transition to metallic conduction takes place at a much lower temperature $T_2 \approx 20$ K. The high resistance in the region of activated conduction has been explained by a reduced mobility or even localization due to "frozen-in" magnetic disorder.[8] Further Cu doping breaks the long-range magnetic order, and spin-glass behavior occurs. The resistivity of the spin-glass samples shows activated behavior in the whole examined temperature range.

In order to explain the very strong dependence of the resistance on spin order in a material with such a low density of states in the conduction band, some authors suggested a magnetic polaron model[5,22,23] i.e., the spin of a conducting electron induces a local distortion of the spin lattice and moves on surrounded by this spin polarization. The transport properties at low temperature should then be dominated by a hopping process. Indeed we find that the resistivity data of Fig. 3(b) and also those obtained on spin-glass samples follow a $\ln \rho \sim T^{-1/4}$ law at temperatures $T \ll T_C$,[8,12] thus suggesting variable-range hopping of spin polarons in a disordered spin lattice.[21,24]

The conception of spin polarons is supported by infrared measurements, which were obtained on sintered samples of $La_{1-z}A_zCu_{1-x}Mn_xO_{3+\delta}$ (A=Sr, Ba).[12,25] A broad peak in optical conductivity at around 2000 cm^{-1} is observed, which is attributed to polaron transport effects. This peak becomes more pronounced as spin disorder is increased by doping of Cu, thus indicating the increased effect of spin polarization on the mobility. Experimental evidence for magnetic polarons above T_C was found by spin-polarized neutron scattering for the very similar compound $Nd_{0.5}Pd_{0.5}MnO_3$.[5]

V. MAGNETORESISTANCE IN THE FERROMAGNETIC REGION

The dependence of the conductivity on the spin order and thus on the magnetization implies a high magnetoresistance in the ferromagnetic region. The highest values should be expected near T_C, because here we find the highest change of saturation magnetization under an applied magnetic field.

Figure 4 shows the temperature dependence of the resistance and magnetoresistance of $La_{1-x}Sr_xMnO_{3+\delta}$ thin films for three compositions $x=0.4$, 0.3, and 0.1. Again we find a cusp in the zero-field resistance (solid line in Fig. 4) at a temperature near T_C, with metallic behavior below and activated behavior above this temperature. The application of an external magnetic field of $\mu_0 H = 5$ T decreases the resistance (dashed line), and the difference to the zero field values is shown by the MR curve (dotted line), which is normalized to the zero-field resistance. The highest MR value is found near to the cusp in resistivity, and the cusp itself becomes smaller and shifts towards higher temperature as the field is increased. Magnetoresistance curves of $La_{0.6}Sr_{0.4}MnO_{3+\delta}$ films at various temperatures are shown in Fig. 5. The MR is normalized to the zero-field values again since no saturation was achieved, but one should notice that, if normalized to the resistance at high field, as is usually done for GMR multilayers, the MR at 230 K exceeds 400% in the 7 T field range.

Films prepared from a $La_{0.67}Ca_{0.33}MnO_3$ target even show an intrinsic GMR of more than 2 orders of magnitude (i.e., 10^4 %) at $T=120$ K. The $R(T)$ curve of this sample, measured at zero field, shows a very high peak near this temperature, which can be completely suppressed by applying a magnetic field of 5 T. At lower temperature ($T<100$ K), we observe spin-glass-like behavior in the magnetization and also in the magnetoresistance. Details about this will be published elsewhere.

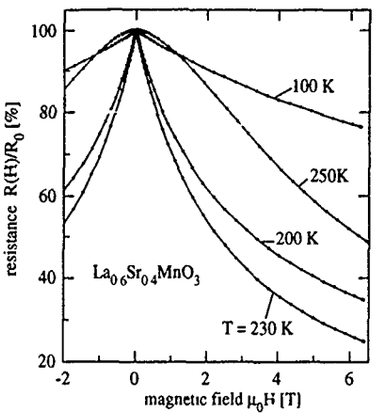

FIG. 5. Magnetoresistance of $La_{0.6}Sr_{0.4}MnO_{3+\delta}$ thin films at various temperatures, normalized to the resistance at $H=0$.

The MR seems not to depend on the relative orientation between magnetic field, electric current, and crystal axes, if one takes into account the different demagnetization factors, thus indicating that the contribution of anisotropic MR can be neglected. At low temperature $T \ll T_C$, the MR decreases again. This is consistent with the conception of a spin-disorder-dependent conductivity which cannot be changed by an applied field if the spin lattice is ordered at zero field.

VI. SUMMARY

In some ferromagnets with composition in the vicinity of a metal-semiconductor transition, an intrinsic GMR effect is possible which by far can be higher than the GMR of metallic multilayers or heterogeneous alloys. This intrinsic GMR occurs in the temperature range around the ferromagnetic transition, and it is not restricted to low temperature, as has been shown for samples with sufficiently high Curie temperature. Zener's model of double exchange gives an impressive imagination of the interplay between magnetic and electric properties. Both are very sensitive to chemical or magnetic disorder, which sometimes can even lead to a localization of charge carriers. The existence of magnetic polarons which determine the transport properties in the ferromagnetic region seems to be a plausible explanation for the observed temperature dependence of the resistance and magnetoresistance.

Colossal magnetoresistance in La-Ca-Mn-O ferromagnetic thin films (invited)

S. Jin, M. McCormack, and T. H. Tiefel
AT&T Bell Laboratories, Murray Hill, New Jersey 07974

R. Ramesh
Bellcore, Redbank, New Jersey 07701

A colossal magnetoresistance effect with more than a thousandfold change in resistivity ($\Delta R/R_H$=127 000% at 77 K, H=6 T) has been obtained in epitaxially grown La-Ca-Mn-O thin films. The effect is negative and isotropic with respect to the field orientations. The magnetoresistance is strongly temperature dependent, and exhibits a sharp peak that can be shifted to near room temperature by adjusting processing parameters. Near-room-temperature $\Delta R/R_H$ values of ~1300% at 260 K and ~400% at 280 K have been observed. The presence of grain boundaries appears to be detrimental to achieving very large magnetoresistance in the lanthanum manganite films. The orders of magnitude change in electrical resistivity could be useful for various magnetic and electric device applications.

I. INTRODUCTION

Perovskite-like oxide of lanthanum manganite ($LaMnO_3$) exhibits both strong ferromagnetism and metallic conductivity when La ions (3+ valence) are partially substituted with 2+ valence ions such as Ca, Ba, Sr, Pb, and Cd. This results in a Mn^{3+}/Mn^{4+} mixed valence state creating mobile charge carriers and canting of Mn spins.[1–10] The unit cell of a perovskite ABO_3 is shown in Fig. 1, where A at the corners represents a large ion such as La^{3+}, Nd^{3+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Pb^{2+}, B at the center of the cube stands for a small ion such as Mn^{3+}, Mn^{4+}, Cr^{3+}, Fe^{3+}, Ti^{4+}, and O at the center of the faces represents O^{2-}. The ionic radii of the elements pertinent to the manganites are listed in Table I. These elements form either simple $AMnO_3$-type or mixed (A+A′) (B+B′) MnO_3-type perovskites following Goldschmidt's perovskite stability criterion on ionic radii, i.e., the ratio $(r_A+r_O)/(r_B+r_O)\sqrt{2}$ should be approximately unity.[1] (r_A, r_B, r_O represent the radii of ions A, B, and O, respectively.)

Thin films of La-manganite thin films have recently been prepared and their magnetoresistance (MR) behavior has been reported for La-Ba-Mn-O (Ref. 11) (with the MR ratio of ~150% at room temperature) and La-Ca-Mn-O (Ref. 12) (MR ratio of ~110% at 220 K and near zero at room temperature). The MR ratio is defined here as $\Delta R/R_H = (R_H - R_0)/R_H$ where R_0 is the zero-field resistance and R_H is the resistivity in the applied magnetic field, e.g., H=6 T. These oxide films exhibited large magnetoresistance comparable to the higher end of the values for the so-called "giant-magnetoresistance(GMR)"-type materials of metallic multilayer or heterogeneous films[13–20] with the MR values typically in the range of 5–150%.

In this article we report the electrical, magnetic, and magnetoresistance behavior in epitaxial La-Ca-Mn-O films with extraordinary MR values in excess of 100 000%, about three orders of magnitude greater than were previously reported for the GMR-type or La-manganite films. Some potential applications of the material are also discussed.

II. EXPERIMENTAL PROCEDURE

Thin films of La-Mn-Ca-O, ~1000 Å thick, were deposited on (100) $LaAlO_3$ substrates by pulsed laser deposition (PLD). The substrate temperature was 650–700 °C, and the oxygen partial pressure in the chamber was maintained at 100–300 mTorr. The nominal target composition was $La_{0.67}Ca_{0.33}MnO_x$. The chemical composition of the depos-

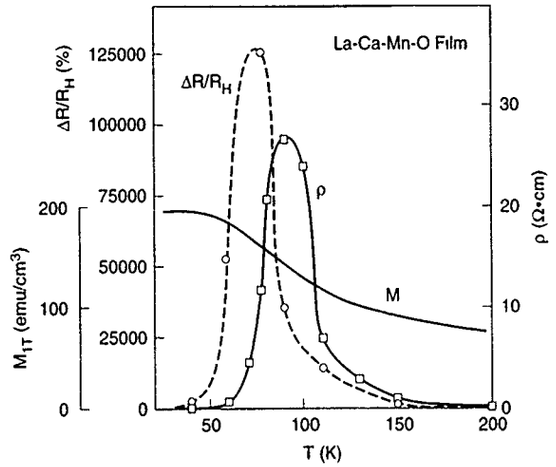

FIG. 3. ρ, $\Delta R/R_H$, and M vs T curves for the epitaxial La-Ca-Mn-O film

ited film was found to be similar to that of the bulk target used for the deposition, as indicated by scanning electron microanalysis and Rutherford backscattering analysis. X-ray-diffraction and rocking angle analysis indicate that the films have the perovskite-type cubic structure with a lattice parameter of $a=3.89$ Å (or $a=7.78$ Å from the crystallographic point of view) and grow epitaxially on the $LaAlO_3$ substrate ($a=3.79$ Å).

The electrical resistance and magnetoresistance of the films were measured as a function of temperature and magnetic field by the four-point technique (using a constant current) in a superconducting magnet with the maximum applied field of $H=6$ T. For most of the films the field direction was parallel to the current direction. Some of the measurements were carried out with the field applied perpendicular to the current direction in the film (using either in-plane field or perpendicular field). The MR behavior in the La-Ca-Mn-O films is almost always negative and essentially isotropic with respect to the field direction if the demagnetizing factor is taken into consideration. The M-H loops were obtained by using a vibrating sample magnetometer with the maximum field of $H=1$ T. The transmission electron microscopy (TEM) was carried out by using JEOL 4000 microscope operated at 400 kV. The samples were thinned by ion milling.

III. RESULTS AND DISCUSSION

The La-Ca-Mn-O films in the as-deposited condition exhibit low MR ratios of typically less than ~500% over a broad temperature range of 50–300 K (low MR only in a relative sense as this is still quite impressive). It has been found that a post-heat treatment of the deposited films is essential in order to maximize the MR behavior.[21] The highest MR ratio so far has been obtained by heat treatment at 900 °C/30 min. in an oxygen atmosphere (3 atm oxygen). As shown by the R vs H curves in Fig. 2 the La-Ca-Mn-O film exhibits a very large magnetoresistance value of 127 000% at 77 K (more than a thousandfold decrease in resistivity). The zero-field resistivity of the film, $\rho\sim11.6$ Ω cm ($R=1.35$ MΩ for the sample size ~1000 Å thick×2 mm wide×4 mm long), decreased in the presence of applied field $H=6$ T to ~9.1 mΩ cm ($R=1.06$ KΩ). The 77 K data indicate that the most significant portion of the resistivity drop occurs at $H<2$ T. The 127 000% MR value in this film is colossal when compared to the 5%–150% magnetoresistance in the GMR multilayer films. As this particular film has been heat treated so as to exhibit the peak MR value near the liquid-nitrogen temperature (77 K), other measurement temperatures gave lower MR ratios, e.g., 14 400% at a higher temperature of 110 K and 54 100% at a lower temperature of 60 K as shown in Fig. 2.

Shown in Fig. 3 are the temperature dependence characteristics of ρ, $\Delta R/R_H$, and M of the La-Ca-Mn-O film. As is evident in the figure, the ρ vs T curve exhibits a relatively sharp cusp at ~95 K with the film showing semiconductor behavior (i.e., a negative $d\rho/dT$) above and metallic behavior (a positive $d\rho/dT$) below this temperature. The temperature at which the magnetoresistance ($\Delta R/R_H$) of the film is maximum is almost invariably located in the metallic-behavior region on the left-hand (low-temperature) side of the resistivity peak. It is interesting to note that the magnetoresistance peak occurs at the temperature where the resistivity is roughly one-half of the peak resistivity or near the inflection point of the curve.

Also shown in Fig. 3 is the magnetization M (at $H=1$ T) versus temperature curve for the La-Ca-Mn-O film. It is evident that the film is strongly ferromagnetic with $M\sim200$ emu/cm^3 at 50 K and $M\sim100$ emu/cm^3 at 150 K. The M-H loops measured at various temperatures are given in Fig. 4. The loops exhibit magnetic hysteresis with coercivity H_c of about 30–50 Oe.

The mechanism(s) responsible for the very large magnetoresistance observed in the La-Ca-Mn-O films appear(s) to be related to the semiconductor-to-metal transition, however, the exact mechanism(s) are not clearly understood at the moment. Previous reports suggested the possibility of spin-disorder scattering, magnetic polaron hopping, or critical magnetic scattering for the relatively small MR effect present

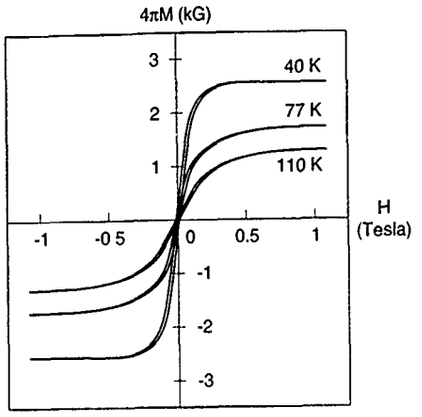

FIG. 4. Magnetization loops for the La-Ca-Mn-O film.

in their La-manganite films.[11,12] However, the fact that the peak in magnetoresistance in the present La-Ca-Mn-O film occurs, not near the magnetic transition temperature where M is near zero, but in the temperature region where M is still substantial (Fig. 3), indicates that spin-disorder scattering is not likely to be the major contributing factor. X-ray-diffraction analysis of the La-Ca-Mn-O film of Fig. 3 at various temperatures shows that there is no change in the cubic crystal structure (no phase transition) in the range of 10–300 K. The resistivity behavior near the temperature of peak MR suggests that the very large magnetoresistances observed are related to the semiconductor-to-metal transition. Further study is required to elucidate the underlying mechanisms for the colossal magnetoresistance in the present La-Ca-Mn-O film.

If the as-deposited film is heat treated for a longer time, e.g., 900 °C/3 h/3 atm O_2, the temperature of peak magnetoresistance is shifted to a higher temperature of ~100 K with a somewhat diminished MR value of $\Delta R/R_H \sim 11\,000\%$ at $H=6$ T. At 77 K and at a lower field, e.g., $H=1000$ Oe, the MR ratio is ~28%. A crude experiment to estimate the local-field-sensing capability of this film has been carried out at the liquid-nitrogen temperature as follows. A magnetic pen (a small Nd-Fe-B magnet attached at the end) was brought to within about 1 mm vertically of the La-Ca-Mn-O film (2 mm×3 mm×1000 Å thick). The magnetic field from the pen at this distance was ~1000 Oe; however, because of the near-perpendicular orientation of the field and the associated demagnetizing factor, the actual effective field on the film is estimated to be much lower than ~900 Oe. The film has the resistance $R=15.9$ kΩ (or $\rho=106$ mΩ cm) at 77 K. The change in voltage output in the film by the approaching field was measured by the four-point technique using a constant current of 1 mA. The zero-field voltage of 15.9 V was altered to 14.6 V when the magnetic pen came near the film with the significant sensor voltage signal ΔV of 1.3 V (or ~8% change). At room temperature a measurement with a similarly sized film with slightly modified composition of $La_{0.55}Ca_{0.25}Sr_{0.08}MnO_x$ ($\rho \sim 1.4$ mΩ cm, $R \sim 280$ Ω) gave a sensor voltage output ΔV of ~13 mV (or ~4.6% change), a sufficient signal for many sensor applications. As the ΔV signal in the sensor is expected to decrease with the distance

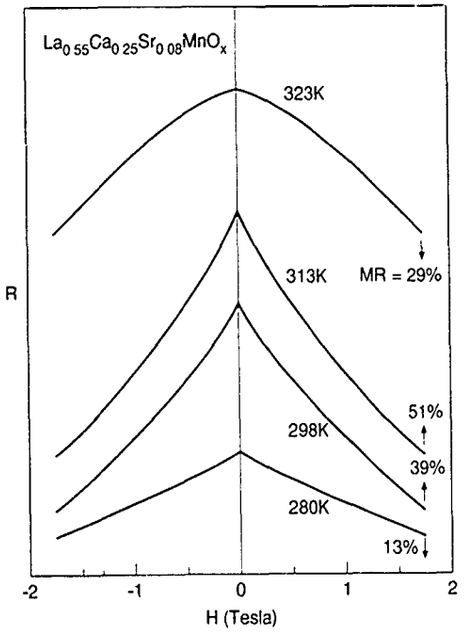

FIG. 5. R vs H curves for the La-Ca-Sr-Mn-O film.

away from the sensor, the magnetoresistive sensor (or an array of sensors) can be used as a position sensing device.

The substantially higher electrical resistivity in the La-Ca-Mn-O films, typically 2–4 orders of magnitude higher than the metallic magnetoresistive materials such as the 80Ni-20Fe Permalloy, could be an advantage for field sensing as the sensor voltage output ($\Delta V/\Delta H$ or $\Delta R/\Delta H$) is that much larger. The R vs H curve for this La-Ca-Sr-Mn-O film at room temperature is approximately linear for a relatively wide range of applied field,[22] as shown in Fig. 5. Thus, the MR ratio of 4.6% at $H \sim 1000$ Oe is equivalent to about 0.046% MR for a lower field of ~10 Oe (this is about the level of field strength of interest for magnetic recording read head). However, as the electrical resistance of this oxide film is about two orders of magnitude higher than that of the Permalloy (with the MR ratio on the order of 3% for $H=10$ Oe), the field-sensing output voltages turn out to be comparable for the two materials at the same level of sensor current. For a constant current of 1–10 mA, the ΔV voltage signal from this unoptimized film for $H=10$ Oe would be 0.13–1.3 mV, comparable to the ΔV value from the Permalloy film with the same dimension.

The magnetoresistive properties of the La-manganite films can be used for a number of other applications. An example is a magnetoresistive microphone design[23] such as schematically illustrated in Fig. 6. A small, La-Ca-Sr-Mn-O–type MR sensor, about 2×4 mm^2 in size, was mounted on a plastic diaphragm. As sound waves with varying intensity hit the diaphragm and make it vibrate, the MR sensor is moved in relation to the magnet that supplies a gradient field. The resulting change in the magnetic-field intensity on the sensor causes a change in resistivity, which in turn changes the output voltage ΔV. Shown in Fig. 7 is a schematic diagram illustrating a circuit configuration for the microphone device. The sensor signal, many mV even in the unamplified condi-

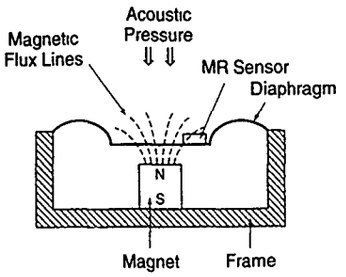

FIG. 6. A magnetoresistive microphone design.

tion, Fig. 8, decreases with the distance from the sound source as is expected.

The MR behavior of the La-Ca-Mn-O film depends not only on the specifics of post-heat treatment but also on a number of other composition and processing details including various film deposition conditions. For example, a higher oxygen partial pressure p_{O_2} during deposition tends to produce films with higher temperature of peak resistance. The magnetization especially near room temperature also increases noticeably with p_{O_2}. A film deposited at p_{O_2}~300 mTorr gives near-room-temperature magnetoresistance values of $\Delta R/R_H$~1300% at 260 K and ~470% at 280 K as shown in Fig. 9. (Because of the cryostat operation in the superconducting magnet used, the MR measurement at 300 K was difficult.) The film is strongly magnetic at these temperatures with $4\pi M$ in excess of 2000 G. The exact nature of this change in MR behavior with the oxygen partial pressure is not clearly understood. Further investigations are underway to find out if it is caused by the change in chemistry (e.g., oxygen or cation stoichiometry) or structure (e.g., degree of epitaxy, lattice parameter, nature and density of defects, etc.).

It is not clearly understood why our La-Ca-Mn-O films exhibit the magnetoresistance effect as much as three orders of magnitude larger than was reported previously on similar La-manganite films.[11,12] It may be attributable to a number of differences in composition and processing details. The presence of grain boundaries appears to be very detrimental to achieving high MR values, based on the following observations: (i) Polycrystalline bulk La-Ca-Mn-O samples of similar composition exhibit low MR values of ~100% or less between 4.2 and 300 K; (ii) nonepitaxial (nonsingle-

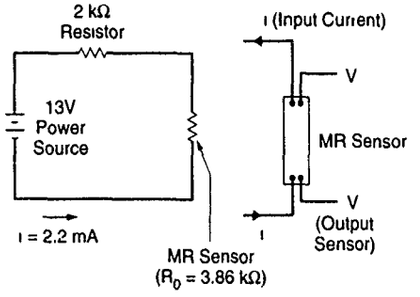

FIG. 7. Schematic diagram illustrating a circuit configuration for the microphone device.

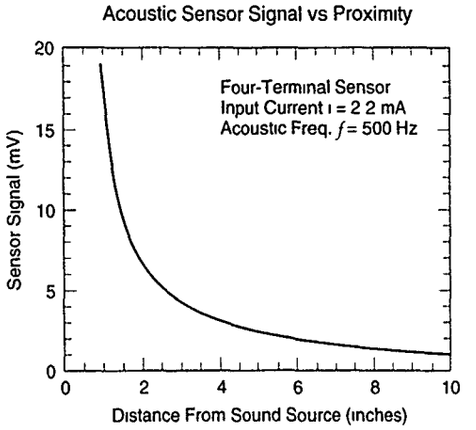

FIG. 8. Sensor signal vs proximity to the sound source for the microphone device of Fig. 6.

crystalline) films deposited on substrates with a greater lattice mismatch [such as Si, (100)MgO] or on polycrystalline substrates (such as yttria-stabilized zirconia) also yield low MR values of less than ~200%. The data previously reported on La-manganite films[11,12] all fall in the similarly low MR value regime. It is also noteworthy that no major difference in MR values was observed between the film and bulk, polycrystalline La-Ba-Mn-O, both exhibiting low MR values.[11] These observations strongly suggest that single crystallinity (a high degree of epitaxy and the absence of grain boundaries), such as shown by TEM analysis over large area and x-ray analysis for the La-Ca-Mn-O film, is a necessary condition for obtaining the very large magnetoresistance such as reported in this work. The single-crystalline nature of the film as well as the near-perfect epitaxy across the $LaAlO_3$/La-Ca-Mn-O interface is evident from Fig. 10.

The possible effect of grain boundaries on MR behavior is a very interesting subject for further investigation. In the La manganites, high electrical resistivity is a prerequisite to the occurrence of large magnetoresistance. The bulk, polycrystalline La-Ca-Mn-O material is too conductive (ρ<50 mΩ cm at 4.2–200 K) to exhibit very large magnetoresistance. Whether the grain boundaries in the La manganites

behave like "weak links" that short out the intragranular, high MR regions and, if so, what the underlying cause behind such a behavior is, needs to be investigated.

IV. SUMMARY

Colossal magnetoresistance in excess of 100 000% at 77 K and 1300% near room temperature has been obtained in epitaxially grown, single-crystalline La-Ca-Mn-O films. These values are orders of magnitude higher than those previously reported for the GMR multilayer films and La-manganite films. The magnetoresistance behavior appears to be related to the semiconductor-to-metal transition. The fact that the electrical resistivity of the material can be manipulated by applied field to a value orders of magnitude different could be exploited for various technical applications.

Giant magnetoresistance in *f*-electron systems (invited) (abstract)

Tadao Kasuya and Takashi Suzuki
Physics Department, Tohoku University, Sendai 980, Japan

Various kinds of giant magnetoresistance have been observed. In the present report, we concentrate on the f-electron systems, particularly on rare earth compounds, and summarize the results by classifying according to mechanisms. One important category is concerning the magnetic impurity state in a doped magnetic semiconductor with a fairly wide band gap. A typical classical example is EuO with O vacancies, in which two conduction electrons with opposite spin directions are trapped at each vacancy. The applied field aligns the spin direction, induces magnetic polaron, expands the extension of the impurity state, and causes a large decrease in resistivity. Another typical example is $Gd_{3-x}S_4$, with x near $\frac{1}{3}$ namely, near Gd_2S_3, in which only a small amount of conduction electrons exists below or around the mobility edge. This system is characteristic in the sense that a strong band tail exists nearly independently on the number of doped carrier. A strong tendency to form magnetic polaron exists and various anomalous properties including giant magnetoresistance is observed. Recently, we performed an extensive study on this material to reveal the fundamental mechanism. Some details will be reviewed. Another category is the intrinsic character, even though it is modified substantially by defects in the real materials. A typical prototype is EuB_6, a typical narrow gap magnetic semiconductor. Applied field causes a ferromagnetic alignment of $4f$ spins, which causes overlapping between the up spin conduction band and the up spin valence band through the d-f exchange and p-f mixing interaction causing the system into a semimetallic state. This further accelerates the $4f$ spin alignment. To see the real intrinsic mechanism, the sample should be very pure and the most suitable samples for this purpose are Ce and Yb monopnictides. Recently, we performed an extensive investigation on a series of the above materials and found various novel characteristic properties, including both giant positive and negative magnetroresistances. A detailed summary is planned.

The spin dynamics in the metallic cuprates are studied theoretically. In the normal state, it is demonstrated that the interplay of correlation effects and fermiology lead to a natural understanding of the contrasting wave vector dependences in the neutron scattering cross sections of the two best characterized cuprates: LaSrCuO and YBaCuO, as well as the anomalous frequency and temperature dependences in the neutron scattering cross sections and in the NMR relaxation rates $1/T_1$ and $1/T_{2G}$. In the superconducting state, the compatibility of the d-wave pairing state with magnetic data is explored.

I. INTRODUCTION

In order to address the origin of high temperature superconductivity, it is essential to understand the nature of the low lying excitations in the metallic cuprates. In this article, we focus on the spin excitations. In conventional metals, the spin dynamics are described by an itinerant picture based on the particle-hole excitation spectrum and the dynamical spin susceptibility is given by the Lindhard function. Such a simple picture does not apply in the copper oxides.

We start the discussion with the stoichiometric compounds such as La_2CuO_4 and $YBa_2Cu_3O_6$. They are insulators with a charge gap of the order of 2 eV. The insulating behavior is unexpected from the one-electron picture since the outermost copper band is half filled. Furthermore, it is unusual compared to band insulators in that spin excitations are not gapped. In fact, an antiferromagnetic ordering is developed at low temperatures.[1] In the paramagnetic phase, the spin dynamics have been studied using both low energy and high energy inelastic neutron scattering, nuclear quadrupole resonance (NQR), and Raman scattering experiments.[1–4] These data have been successfully analyzed in terms of interacting spin waves in the two-dimensional Heisenberg model on a square lattice.[5] In this picture, spins are localized at the copper sites within each CuO_2 layer, and are coupled with each other through essentially a nearest-neighbor Heisenberg coupling. These features are characteristic of a Mott (charge-transfer) insulator and explicitly establish the existence of a strong on-site Coulomb repulsion among the copper d electrons.

As the system is doped away from half filling, the magnetic order quickly vanishes, and an insulator to metal (superconductor) transition sets in. In the metallic cuprates, antiferromagnetic fluctuations have also been observed, mainly through NMR/NQR and inelastic neutron scattering experiments.[6,1] In the context of a conventional theory of spin fluctuations in simple metals, the NMR/NQR data appear to be highly anomalous: (a) The copper-site spin-lattice relaxation rate, $(1/T_1)_{Cu}$, is strongly enhanced in magnitude. Its temperature dependence deviates strongly from the usual linear behavior.[6] Such an anomalous temperature dependence is also reflected in the Gaussian component of the transverse relaxation rate, $1/T_{2G}$.[7] (b) At the same time, the oxygen-site spin-lattice relaxation rate, $(1/T_1)_O$, is almost linear in temperature, and has a nominal Korringa ratio of order 1.[8] The neutron scattering data are also puzzling: (c) The momentum dependences in the two best-characterized cuprates, YBaCuO and LaSrCuO, are quite different. In YBaCuO, antiferromagnetic spin fluctuations are commensurate. The commensurate peaks are broad, with essentially temperature-independent widths.[9,10] In LaSrCuO, spin fluctuations are sharply peaked at incommensurate wave vectors $\mathbf{Q}^*$;[11,12] (d) Within the lightly doped nonsuperconducting LaSrCuO system[13] the cross sections are found to scale with ω/T. Systematic studies of the temperature and frequency dependences of the cross sections for systems closer to optimal doping have, however, revealed low energy scales in YBaCuO.[9,10] Comparable experiments are still under way for the normal state of superconducting LaSrCuO.

Given that the conduction electrons in the cuprates are strongly interacting with each other, it is perhaps not surprising that the magnetic data appear to be anomalous compared to conventional metals. However, the exact nature of the spin excitations in a doped Mott–Hubbard system is not known. In particular, it is not clear *a priori* whether doped holes leave the localized spins of the half filled cuprates intact leading to a frustrated spin system, or they manage to convert the localized spins into renormalized quasiparticles. Therefore, an analysis of the spin dynamical data of the metallic cuprates can help clarify the nature of these spin excitations and the residual magnetic coupling. It also allows us to discuss their implications of magnetic data for the nature and the origin of superconductivity. This brief review summarizes our own work[14–18] in this area and is not intended to be comprehensive.

II. DYNAMICAL SPIN SUSCEPTIBILITY

The inelastic neutron scattering cross section is directly related to the spin structure factor $S(\mathbf{q},\omega)$,

 0021-8979/94/76(10)/6935/6/$6.00 © 1994 American Institute of Physics

$$d^2\sigma/d\Omega_q\, d\omega \sim S(\mathbf{q},\omega). \tag{1}$$

$1/T_1$ is the rate at which the nuclear magnetization relaxes towards equilibrium and is given by

$$\left(\frac{1}{T_1}\right)_r \sim \sum_{\mathbf{q}} A_r^2(\mathbf{q}) S(\mathbf{q},\omega_N \to 0), \tag{2}$$

where ω_N represents the nuclear resonance frequency which is essentially zero compared to typical electronic energies, and $A_r(\mathbf{q})$ is the hyperfine coupling constant for nuclei r (copper or oxygen). Through the fluctuation-dissipation theorem, $S(\mathbf{q},\omega)=\chi''(\mathbf{q},\omega)/(1-e^{-\omega/T})$, where $\chi''(\mathbf{q},\omega)$ is the imaginary part of the dynamical spin susceptibility. Finally, the Gaussian component of the Cu-site spin-echo decay rate, $1/T_{2G}$, is determined by the coupling between the copper nuclear spins. Through the usual Ruderman–Kittel–Kasuya–Yosida (RKKY) mechanism, the indirect contribution can be related to the static spin susceptibility $\chi(\mathbf{q})$ and is given approximately by[19]

$$\frac{1}{T_{2G}} \sim \left[\sum_{\mathbf{q}} F(\mathbf{q})^4 \chi(\mathbf{q})^2 - \left(\sum_{\mathbf{q}} F(\mathbf{q})^2 \chi(\mathbf{q}) \right)^2 \right]^{1/2}, \tag{3}$$

where $F(\mathbf{q})$ is the out of plane component of $A_{\mathrm{Cu}}(\mathbf{q})$.

In conventional metals, $\chi''(\mathbf{q},\omega)$ has the Lindhard form, $\chi''(\mathbf{q},\omega) \sim \Sigma_{\mathbf{k}}[f(E_{\mathbf{k}+\mathbf{q}}) - f(E_{\mathbf{k}})]\delta(E_{\mathbf{k}} - E_{\mathbf{k}+\mathbf{q}} - \omega)$. This implies that (a) the $\mathbf{q}$ dependence in the neutron scattering cross section at low energies reflects the geometry of the Fermi surface. Physically, only single-particle states close to the Fermi level can contribute to the low energy spin fluctuations; (b) the energy scale for the temperature and frequency dependences is determined by the Fermi energy which is of the order of eV or 10 000 K; (c) $1/T_1$ is linear in temperature, and satisfies the Korringa law, $1/T_1 T\chi^2 = 1$, where χ is the static uniform magnetic susceptibility. (Here, for simplicity, dimensionless units are used.) Physically, the number of electrons available to flip the nuclear spin is proportional to $TN(E_F)$, and each electron contributes a relaxation rate proportional to $N(E_F)$, where $N(E_F)$ is the density of states at the Fermi level which is also proportional to χ.

To derive the appropriate form of the dynamical susceptibility for the metallic cuprates,[14] we consider the extended Hubbard model defined in a CuO_2 layer

$$H = \sum_{i\sigma} \epsilon_d^0 d_{i\sigma}^\dagger d_{i\sigma} + \sum_i U n_{d,i\uparrow} n_{d,i\downarrow} + \sum_{il\sigma} V_{pd}(d_{i\sigma}^\dagger p_{l\sigma} + \text{h.c.})$$

$$+ \sum_{l_1 l_2 \sigma} t_{l_1 l_2}(p_{l_1\sigma}^\dagger p_{l_2\sigma} + \text{h.c.}). \tag{4}$$

The copper d electrons have an energy level ϵ_d^0 and an on-site interaction U. The oxygen p electrons have a dispersion determined by the hopping matrix elements t_{pp} (nearest neighbor) and t'_{pp} (next nearest neighbor). The two bands are coupled through the hybridization matrix element V_{pd} (nearest neighbor).

At half filling, this model has a Mott (charge-transfer) insulating solution when both the Coulomb repulsion U (taken as infinity here) and the level separation $\epsilon_p - \epsilon_d^0$ are large. The low energy configurations correspond to each copper site occupied by a spin, and each oxygen site fully occupied by electrons, or equivalently, empty of holes. The exchange interaction among the copper spins comes from the superexchange mechanism. Among the excited states that can be virtually occupied, the lowest ones correspond to holes occupying the oxygen orbitals. Since there is only nearest-neighbor hybridization between copper and oxygen orbitals, the dominant contribution to the exchange interaction among the copper spins comes from the nearest neighbor term. Therefore

$$J(\mathbf{q}) = J_0[\cos(q_x) + \cos(q_y)]. \tag{5}$$

This result is quite insensitive to the oxygen dispersion, so long as the (bare) oxygen levels are well separated from the copper level. Such a nearest-neighbor form for $J(\mathbf{q})$ is supported by high energy spin wave measurements on the insulating state.[2]

In the metallic cuprates, one of the key experimental results is the observation of a large Fermi surface with a volume satisfying Luttinger's theorem.[20] This implies that, when a sufficient number of holes are doped into the insulator to make a metallic phase, these holes convert the localized copper spins into itinerant quasiparticles at low energies. Such a picture is also supported by various numerical calculations of the single-particle spectral functions in Hubbard-like models. This picture can be formally implemented in terms of the widely used large N approach to the extended Hubbard Hamiltonian equation (4) (here N is the spin degeneracy). Within the mean field theory, the constraint that there be no double occupancy of a copper site, as a consequence of strong Coulomb interactions, is manifested in the renormalization of the hybridization matrix element, $V_{pd} \to V_{pd}^*$, as well as of that of the copper level, $\epsilon_d \to \epsilon_d^*$. The quasiparticles of the system are described by the renormalized band. Compared to the noninteracting case, the renormalized band has an enhanced mass, and the density of states of the antibonding band has a large asymmetry with respect to the Fermi level.

We have chosen the bare band parameters so that (a) the plasma frequencies of the renormalized band fit those experimentally derived from the Drude-fitted optical conductivity.[21] This constraint assures that the band widths are reasonable; and (b) the correct Fermi surfaces are obtained for both LaSrCuO and YBaCuO. The Fermi surface in YBaCuO is rotated by 45° relative to the diamond shape expected in a nearest-neighbor tight binding, one band model.[20,22] The Fermi surface in LaSrCuO retains a diamond-like shape, though it is somewhat distorted so that the nearly flat regions are closer to the Γ point.[22] While the origins of these differences are not well understood, we are able to arrive at the correct Fermi surfaces through effectively modeling the oxygen dispersion appropriately. Such a modeling of the oxygen dispersion is expected to be reasonable for the discussion of the spin dynamics in the large U limit, since the spin degrees of freedom are mainly associated with the copper states. Finally, our renormalized band structure shows logarithmically divergent van Hove singularities in the single-particle density of states at $(\pm\pi,0)$ and $(0,\pm\pi)$. The separation of the energy at these wave vectors

from the Fermi energy introduces a van Hove energy, ω_{VH}. Due to the different shapes of the Fermi surfaces, ω_{VH} is found to be larger in YBaCuO, of the order of 25 meV, than that in LaSrCuO, which is less than 5 meV.

At a formal level, the superexchange interaction of the metallic phase can be established through analyzing the corrections to the mean field theory, beyond the leading order in $1/N$ expansion.[14] We found that, while the quasiparticle dispersion is determined by the renormalized copper level, ϵ_d^*, and the renormalized hybridization, V_{pd}^*, the relevant quantities for the calculation of the dominant superexchange interaction are the corresponding bare parameters, ϵ_d^0 and V_{pd}. This is not surprising since the superexchange interaction arises from the *virtual* occupancy of the high-lying excited states. A separation of energy scales, therefore, remains and the dominant antiferromagnetic interaction is insensitive to the oxygen dispersion and continues to have the nearest-neighbor form of Eq. (5) for both YBaCuO and LaSrCuO systems, despite their very different Fermi surface shapes.

The dynamical spin susceptibility is found to have the generalized random-phase approximation (RPA) form

$$\chi(\mathbf{q},\omega)\sim\frac{\chi_0(\mathbf{q},\omega)}{1+J(\mathbf{q})\chi_0(\mathbf{q},\omega)}, \tag{6}$$

where $\chi_0(\mathbf{q},\omega)$ is the Lindhard function associated with the renormalized quasiparticle energy dispersion $E(\mathbf{k})$. It should be noted that, this form of the dynamical susceptibility describes the contribution to the spin susceptibility due to the coherent (quasiparticle) part of the single-particle excitation spectra. The incoherent contribution becomes increasingly important at high energies where local-moment behavior is evidenced.

III. SPIN DYNAMICS IN THE NORMAL STATE

A. Wave vector dependence of the inelastic neutron scattering cross sections

In two-dimensional systems, the (dynamical) Kohn anomaly leads to peaks in the imaginary part of the Lindhard function at wave vectors $\mathbf{q}=2\mathbf{k}_F$.[15,23–25] In LaSrCuO, such a Kohn anomaly, along with the nesting enhancement, leads to incommensurate peaks at $\mathbf{Q}^*=\pi(1\pm\delta,1)$, $\pi(1,1\pm\delta)$ (Ref. 26) away from, but close to, $\mathbf{Q}_{AF}=(\pi,\pi)$, as is illustrated in the inset to Fig. 1(a). Since $-J(\mathbf{q})$ is peaked at $\mathbf{Q}_{AF}$, it enhances $\chi''(\mathbf{q},\omega)$ and hence $S(\mathbf{q},\omega)$ around an extended region in the Brillouin zone near $\mathbf{Q}_{AF}$. For moderate values of J_0/J_c (where J_c is the strength of the interaction which gives rise to an actual magnetic instability in the system), the four peak structure is enhanced with overall shape unchanged, as is clearly seen in Fig. 1(a). When projected along two of the four peaks, our results can be favorably compared to the experimental results of Refs. 11 and 12. We have also carried out a detailed analysis of the behavior of the incommensurability as a function of the doping concentration. The large value, together with the strong doping dependence, of the incommensurability observed experimentally[11] can be understood only when strong Coulomb interactions as well as a finite nearest-neighbor oxygen–oxygen hopping matrix element t_{pp} are included.

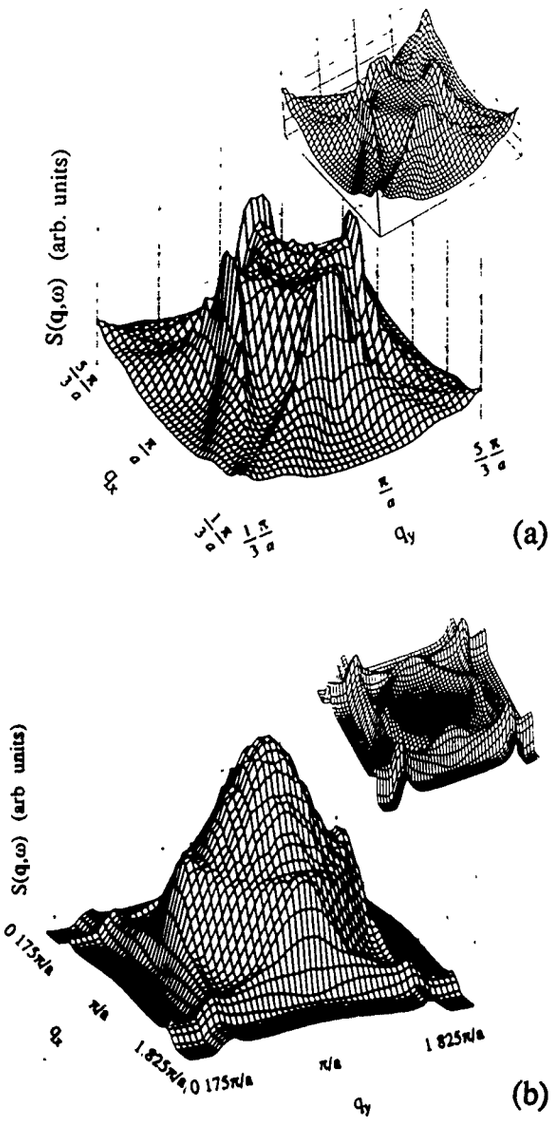

FIG. 1. Calculated $S(\mathbf{q},\omega)$ vs (q_x,q_y) (a) for $YBa_2Cu_3O_{6.7}$ with $J_0/J_c=0.7$ and (b) for $La_{1.82}Sr_{0.18}CuO_4$ with $J_0/J_c=0.6$. The insets give the corresponding results with $J_0=0$. Here the temperature and frequency are 1 and 10 meV, respectively.

We now study the spin dynamics in the YBaCuO family. The $\mathbf{q}$ structure of the Lindhard susceptibility corresponding to the appropriate renormalized band structure with a rotated Fermi surface is shown in the inset to Fig. 1(b). Because of the Fermi surface rotation, the Kohn anomaly induced—and nesting enhanced—peaks are far away from the antiferromagnetic wave vector $\mathbf{Q}_{AF}=(\pi,\pi)$. Therefore, the dynamical susceptibility is essentially featureless near $\mathbf{Q}_{AF}$. The antiferromagnetic interaction enhances the amplitude of $S(\mathbf{q},\omega)$ or $\chi''(\mathbf{q},\omega)$ in the region surrounding $\mathbf{Q}_{AF}$, leading to an essentially commensurate peak shown in Fig. 1(b). When projected along the diagonal direction, our results can be compared favorably to the experimental results of Refs. 9 and 10. Experimentally, in the fully oxygenated system, the half widths correspond to magnetic correlation lengths of around one lattice spacing[27,10] and in the deoxygenated case

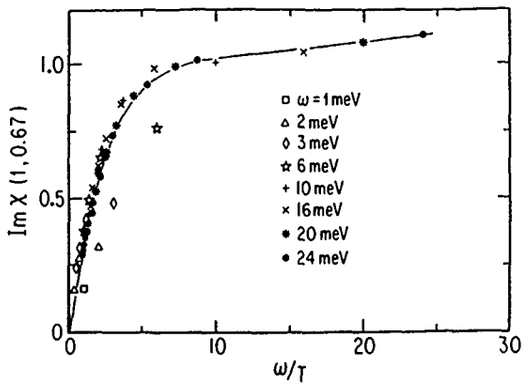

FIG. 2. Normalized $\chi''(\mathbf{q},\omega)$ as a function of ω/T for $La_{1.82}Sr_{0.18}CuO_4$ at the peak wave vector. The solid line represents the scaling curve.

$(YBa_2Cu_3O_{6,7})$ the corresponding length is around two lattice spacings.[9,10] Furthermore, the **q**-integrated structure factor is found to have essentially the same temperature dependence as that of the structure factor at $\mathbf{Q}_{AF}$.[9] In our theory, the fact that J is not particularly close to a magnetic instability yields a relatively broad peak whose width is essentially independent of temperature. This is in contrast with other theories in which longer and strongly temperature-dependent correlation lengths are assumed.[28,29]

The contrasting **q** dependences of the dynamical susceptibilities in LaSrCuO and YBaCuO, therefore, provide direct evidence that the particle-hole continuum associated with the renormalized quasiparticles gives the dominant contribution to the spin dynamics at low energies.

B. Temperature and frequency dependences of the dynamical spin susceptibility

The frequency and temperature dependences of the dynamical susceptibility in the present theory are discussed extensively in Ref. 17. The lowest energy scale is manifested as a weak peak in the frequency dependence of the neutron structure factor, and is found to correspond to the van Hove singularity energy ω_{VH}. Magnetic interactions of moderate strength lower the position of this peak, and considerably enhance the low energy spin fluctuation spectra. These low energy scales can also be illustrated in a scaling plot of the susceptibility in terms of ω/T. In Fig. 2, such a scaling plot is shown for susceptibilities calculated for LaSrCuO at the incommensurate peak position. Since ω_{VH} is small in LaSrCuO, we find that the dynamical susceptibility scales with ω/T until very low temperature and frequency. In YBaCuO system, ω_{VH} is considerably larger, $\omega_{VH}\sim 25$ meV. A deviation from scaling is predicted[16] for YBaCuO, when the frequency is smaller than ω_{VH} *and* the temperature smaller than $T_{VH}\sim\frac{1}{4}\omega_{VH}$. Recent experimental results from Ref. 9 seem to be consistent with this prediction for the case of YBaCuO.

C. NMR/NQR relaxation rates

We now turn to the analysis of the NMR/NQR data. Shown in Fig. 3(a) is the calculated temperature dependence of $1/T_1T$ at the copper site in deoxygenated YBaCuO. The

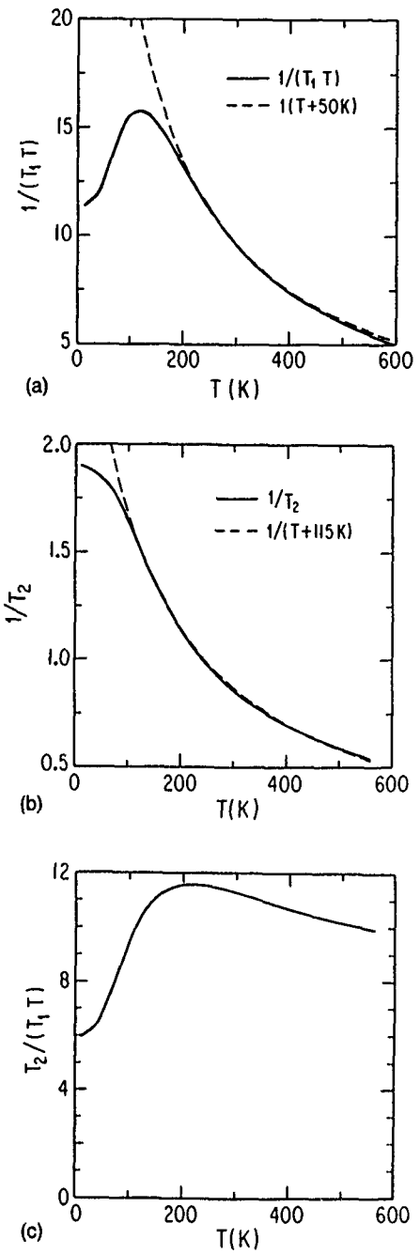

FIG. 3. Calculated temperature dependence of NMR relaxation rates in $YBa_2Cu_3O_{6.7}$: (a) $1/T_1T$; (b) $1/T_{2G}$; and (c) T_{2G}/T_1T. The vertical axes are in arbitrary units.

downturn at low temperatures reflects the van Hove energy scale ω_{VH}. (By contrast, this downturn is not present in the normal state of LaSrCuO since ω_{VH} is much smaller.) At high temperatures $1/T_1$ starts to saturate and $1/T_1T$ exhibits a Curie–Weiss temperature dependence. This temperature dependence is in reasonable agreement with experimental data, as is the enhanced magnitude. We emphasize that, within our analysis, the strong Coulomb correlations lead to two effects. They renormalize the quasiparticle energy spectrum, and induce residual exchange interactions between the quasiparticles. Because of this Coulomb-induced renormalization, we find that there is sufficient spin fluctuation spectral weight to explain the enhanced magnitude in $1/T_1$, without making the

assumption of proximity to a magnetic instability. In this way, we are able to explain both the neutron scattering and the Cu-site NMR results. In LaSrCuO system, this is consistent with the recent results of Walstedt and co-workers.[30] These authors have demonstrated that $(1/T_1)_{Cu}$ measured in the NMR experiments are in quantitative agreement with their counterparts calculated from the incommensurate peaks derived from the neutron scattering experiments.[11] As shown earlier, the incommensurate peaks arise from the the quasiparticle contributions; this quantitative agreement, therefore, reinforces the conclusion that low energy spin dynamics are dominated by quasiparticle contributions.

We have also calculated $1/T_{2G}$. As is seen in Fig. 3(b), a high temperature Curie--Weiss dependence is also reflected in $1/T_{2G}$, consistent with experimental results.[7] The Curie–Weiss behavior for both $1/T_1T$ and $1/T_{2G}$ also implies that the ratio T_{2G}/T_1T is weakly temperature dependent at high temperatures, as is seen in Fig. 3(c). The qualitative behavior is quite similar to the corresponding experimental plot of Takigawa.[7] In our calculations, the high temperature Curie–Weiss behavior for $1/T_1T$ and $1/T_{2G}$ results from the Curie–Weiss behavior for both $\chi'(\mathbf{q},\omega\rightarrow 0)$ and $\lim_{\omega\rightarrow 0}\chi''(\mathbf{q},\omega)/\omega$ over an extended region in the Brillouin zone around $\mathbf{Q}_{AF}=(\pi,\pi)$. The temperature scale is set by the fraction of the Fermi energy further lowered by the exchange enhancement factor. In this way, it reflects the proximity to Mott localization [which is incorporated in $\chi_0(\mathbf{q},\omega)$] *combined with* moderate magnetic interaction effects. By contrast, weak coupling calculations[29] assume that the system is very close to a magnetic instability; this soft spin fluctuation frequency then leads to these very low energy scales, as well as large magnitudes in $1/T_1$. Our result is also in contrast with the essentially temperature independent $1/T_{2G}$ calculated by Littlewood *et al.*[23] within a marginal Fermi liquid framework, in which the magnetic interaction between the quasiparticles is assumed to be zero.

In the strong coupling limit, the renormalized quasiparticle description is in essence a low temperature expansion. At sufficiently high temperatures, this description should break down; instead, the single particle excitations become incoherent, and the spin dynamics should cross over to a local-momentlike behavior. In this way a temperature-independent $1/T_1$ is expected at high temperatures. This physical picture is consistent with recent measurements of $1/T_1$ in LaSrCuO.[3] The situation is very similar to the spin dynamics in heavy fermion metals.[31,32] The precise local-moment dynamics for the cuprates are not known. Recently, based on the phase diagram for the 2D quantum nonlinear sigma model,[5] suggestions have been made that the high temperature local-moment dynamics in the metallic cuprates may show a universal behavior controlled by a zero temperature critical point.[33,34] In particular, a temperature-independent T_{2G}/T_1T has previously been shown to arise within this scheme.[34] In general, it is important to determine, in a given temperature regime, how much of the spin fluctuations can be attributed to the quasiparticle-quasihole continuum contribution, and how much to the local-moment contributions. Neutron scattering results at higher frequencies and temperatures should help clarify this issue, as the dynamical susceptibilities associated with these different contributions are expected to have different forms.

The situation for the oxygen site NMR relaxation rate is more complex. Because the peaks in the dynamical spin susceptibility are strongly *incommensurate* in LaSrCuO, and have a *broad* half-width in YBaCuO, a perfect oxygen form-factor cancellation, based on the transfer-coupling Hamiltonian,[35] is not expected in either system. In the present calculations, within the transfer-hyperfine coupling model, $(1/T_1)_O$ shows considerable deviation from a linear temperature dependence. In the context of the LaSrCuO system, similar conclusions have also been reached.[30] At present, it is not clear whether this means that our understanding about the hyperfine coupling associated with the oxygen nucleus is not complete or an important piece of physics is still missing.

To summarize, the contrasting spin dynamics in LaSrCuO and YBaCuO, and the consistency of the spin fluctuation spectral weights inferred from the neutron scattering cross sections and (Cu-site) NMR relaxation rates, lead us to conclude that, at low temperatures and frequencies the dominant spin fluctuations are described in terms of a particle-hole excitation spectrum associated with renormalized quasiparticles, which interact with each other through an antiferromagnetic interaction of moderate strength. At higher temperatures and frequencies, the relative contributions of the quasiparticle (coherent) part and the local-moment (incoherent) part remain to be determined.

IV. SPIN DYNAMICS IN THE SUPERCONDUCTING STATE

The application of Eq. (6) below T_c is straightforward. We have found that[18] the anomalous temperature dependences at low frequencies observed in neutron measurements[11,12,9] of $S(\mathbf{q},\omega)$ may be compatible with a $d_{x^2-y^2}$ pairing state in both LaSrCuO and YBaCuO. However there are problems with the wave vector dependences of $S(\mathbf{q},\omega)$. Of the two cases, the effects are more striking in YBaCuO. At the lowest temperatures all that contributes to the cross section are processes in which the Lindhard function is not fully "gapped out." These correspond to node-to-node scattering and because the nodal positions are unrelated to the Fermi surface nesting, these low T peaks will not be in the same position as their counterparts in the normal state. In this way the peaks in the structure factor move with decreasing T, from their high T positions to incommensurate positions along the zone diagonal. Similar observations were made first in Ref. 36. The failure of current experiments[11,12,9] to observe this shift in the peak position is thus not consistent with a (clean) d-wave picture.

Recently, similar calculations[37] were performed in the context of a weak-coupling Hubbard Hamiltonian with only first nearest-neighbor hopping integrals. In this case, the real part of $\chi_0(\mathbf{q},\omega)$ and, hence, the exchange enhancement, are strongly peaked at $\mathbf{Q}^*$ both for $T>T_c$ and for $T<T_c$. Therefore, the peak shifts will not occur; rather, the four peaks in the normal state are expected to become sharper. This is illustrated in Fig. 4(a). Such a sharpening of the peaks, however, is not seen experimentally.[11] Furthermore, we have

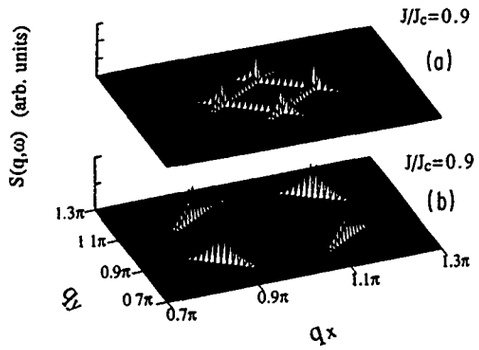

FIG. 4. Calculated $\chi''(\mathbf{q},\omega)$ vs (q_x,q_y) for the tight-binding band (a) with nearest-neighbor hopping only, $t'=0$, and $J/J_c=0.9$; and (b) with additional nonzero next-to-nearest-neighbor hopping term $t'=0.2t$ and $J/J_c=0.9$. Here $T=3$ K and $2\Delta_0/kT_c\sim 3$ 5.

found that this result is dependent on the specific features of the band structure. Our studies of this model and its three band extension reveal that, when moderately strong second nearest-neighbor hopping integrals are included, the exchange enhancement is no longer sharply peaked at $\mathbf{Q}^*$, and a shift in the position of the $\mathbf{q}$ dependent peaks occurs no matter how strong the exchange enhancements are. Such a second nearest-neighbor hopping matrix is necessary to arrive at more realistic Fermi surface shapes, correct Hall coefficient as well as to explain the large value of the incommensurability in the normal state.[17] In Fig. 4(b) we have plotted the corresponding result for $t'=0.2t$ with a very strong exchange enhancement, $J/J_c=0.9$; a shift of the peak positions is evident.

On this basis, it may be argued that magnetic data are not fully consistent with the d-wave picture. Nevertheless, one can not rule out the effects of impurity scattering which may smear the density of states and thereby affect the position of the $\mathbf{q}$-dependent peaks. It should be noted, however, that impurity effects in an anisotropic superconductor give rise to pair breaking and thereby a significant depression of T_c.[38] Furthermore, they should also be incorporated in the theoretical interpretations[36,39] of the Cu and O NMR data in $YBa_2Cu_3O_7$,[40] which have been argued to give strong support for a $d_{x^2-y^2}$ pairing state. Whether one can arrive at a "dirty d-wave" scenario for neutron and NMR data which at the same time leaves T_c unchanged has not yet been established.

ACKNOWLEDGMENTS

Hydrostatic pressure on $HgBa_2CaCu_2O_{6+\delta}$ and $HgBa_2Ca_2Cu_3O_{8+\delta}$

F. Chen, L. Gao, R. L. Meng, Y. Y. Xue, and C. W. Chu
Department of Physics and Texas Center for Superconductivity, University of Houston, Houston, Texas 77204-5932

The superconducting transition temperature T_c and its pressure dependence dT_c/dP of $HgBa_2CaCu_2O_{6+\delta}$ (Hg-1212) and $HgBa_2Ca_2Cu_3O_{8+\delta}$ (Hg-1223) were measured up to 17 kbar. T_c increases with pressure approximately linearly for both compounds before oxidation. However, the nonlinearity in the T_c-P correlation shows up after oxidation in both compounds. For Hg-1212, the average dT_c/dP decreases as oxygen doping increases, while it increases in Hg-1223. These observations are in conflict with the modified pressure-induced charge-transfer model, but might be attributed to the possible existence of fine electronic structure. These observations suggest that a T_c much higher than 140 K might be achievable in Hg-1223 by means of higher physical or chemical pressure.

I. INTRODUCTION

Previous pressure studies on high T_c cuprates at various oxidation states show that the T_c changes linearly at pressures between 0 and 20 kbar.[1] This can usually be explained by pressure-induced charge-transfer,[2] i.e., dT_c/dP decreases with the carrier concentration n, which increases with oxidation. Soon after the discovery of the superconducting homologous series $HgBa_2Ca_{n-1}Cu_nO_{2n+2+\delta}$ [Hg-12(n-1)n],[3] band-structure calculations showed that the electronic structure of these compounds was strongly affected by the van Hove singularity and evolved with doping rather abnormally,[4] suggesting that their pressure effect dT_c/dP might be unusual. After samples of these compounds with different oxygen stoichiometry became available, we systematically studied their pressure dependence.

A positive dT_c/dP was observed in all $HgBa_2CaCu_2O_{6+\delta}$ (Hg-1212) and $HgBa_2Ca_2Cu_3O_{8+\delta}$ (Hg-1223) samples. For the as-prepared Hg-1212 samples with $T_c \sim 112$ K, T_c increased linearly with pressure at a rate $dT_c/dP = 0.22 \pm 0.02$ K/kbar throughout our pressure range. For oxygenated Hg-1212 samples with $T_c \sim 119$ K, T_c increases with pressure at a similar rate below ~4 kbar, but the rate of increase decreases to 0.11 ± 0.02 K/kbar thereafter. Although the nonlinear T_c-P correlation is rather unusual, the smaller average dT_c/dP after oxygenation is consistent with the charge-transfer model,[2] which suggests that the average dT_c/dP decreases with the carrier concentration n. The dT_c/dP of several Hg-1223 samples was also measured. The dT_c/dP of vacuum-annealed and as-synthesized samples was independent of P. However, the T_c vs P of oxygenated Hg-1223 shows positive curvature above 12 kbar. Unlike that for Hg-1212, the overall dT_c/dP for Hg-1223 increases with oxidation, which is in direct conflict with the modified charge-transfer model.[2]

II. EXPERIMENT

High quality samples were prepared using the controlled vapor/solid reaction (CVSR) technique.[5] The samples are ~90% pure with ~10% $CaHgO_2$ and $Ba_2Cu_3O_{5+\delta}$ impurities. Structure characterization was carried out by x-ray diffraction using a Rigaku D-MAX/BII powder diffractometer. The dc magnetic susceptibility (χ_{dc}) of samples at ambient pressure was measured by a quantum design superconducting quantum interference device (SQUID) magnetometer. A standard inductance bridge, operated at 16 Hz in an ac field of ~5 Oe peak to peak, was employed to determine the ac magnetic susceptibility (χ_{ac}) under pressures. The standard four-lead measurement was applied to measure resistivity. Hydrostatic pressure up to 18 kbar was generated at room temperature inside a Teflon cup housed in a Be-Cu high pressure clamp,[6] using 3M Fluorinert as the pressure medium. The pressure was determined by a Pb-manometer placed next to the sample. The temperature was measured by an alumel-chromel thermocouple above 30 K and a Ge thermometer below 30 K.

III. RESULTS AND DISCUSSION

Four samples of Hg-1212 were characterized. Samples A and C were as synthesized with $T_c \sim 112$ K. Samples B and D were annealed in 1 atm O_2 at 300 °C for 30 h with $T_c \sim 119$ K and were determined to be overdoped. The χ_{dc} of samples A, B, and D are shown in Fig. 1. The transition is quite sharp and the superconducting volume fraction is large (especially for sample D). The onset and midpoint of T_c (T_{co} and T_{cm}) as determined by ac-susceptibility measurements at various pressures are shown in Fig. 2. The T_{co}'s of sample A and C have the same trend as the T_{cm}'s although they are not shown in the figure. The T_{cm} of sample D is not well defined due to poor grain coupling and thus not shown. T_c increases linearly with P at a rate of 0.22 ± 0.02 K/kbar for samples A and C. For samples B and D, T_c increases at a rate of ~0.23 K/kbar below 4 kbar. The rate fell to 0.11 ± 0.03 K/kbar above 4 kbar. As proposed by the modified charge-transfer model,[2] the overall dT_c/dP decreases as oxidation increases.

Five samples from two different batches of Hg-1223 were also examined. Sample V was as synthesized with $T_c \sim 117$ K. Sample W, with $T_c \sim 79$ K, was obtained by high vacuum annealing at 450 °C for 1 day. Samples X, Y, and Z were annealed in flowing oxygen at 300 °C for 1 day, with $T_c \sim 135$ K. Figure 3 shows T_c versus pressure for Hg-1223. The T_c's for samples V, X, Y, and Z were measured resistively. Although we only plotted T_{cm} for these samples, the behavior of T_{co} and T_{cz} (zero point of the transition) is similar. A long tail in the superconducting transition was ob-

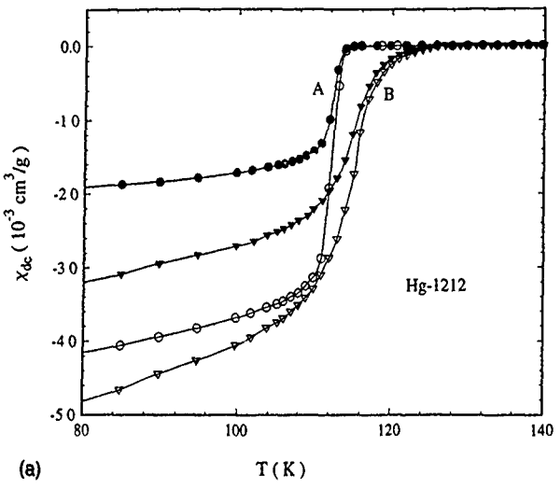

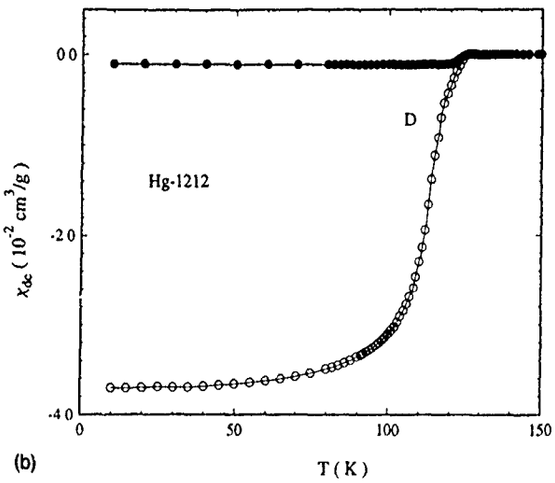

FIG. 1. (a) χ_{ac} vs T for Hg-1212 sample A and B. (b) χ_{dc} vs T for Hg-1212 sample D. Filled symbol: field cooling; open symbol: zero-field cooling.

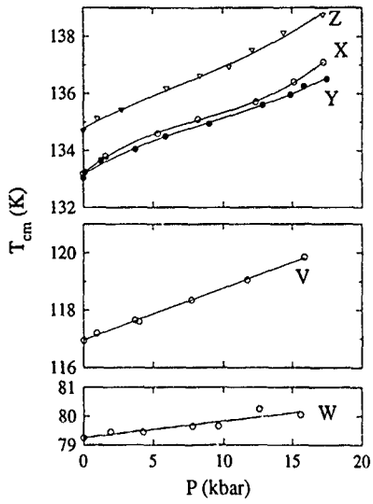

FIG. 3. T_{cm} vs P for Hg-1223 samples V, W, X, Y, and Z.

served for the sample W, which might be due to damage caused to the grain boundaries during annealing. Therefore, the T_c of this sample was measured magnetically and T_{cm} was obtained from the peak of $d\chi_{ac}/dT$. We can see clearly that the average dT_c/dP increases with oxidation. From thermoelectric measurements, we extracted the carrier concentration n by an empirical law.[7] Figure 4 shows the average dT_c/dP vs n for Hg-1212 and Hg-1223.

Recently, a study[2] of combined effects of pressure and doping on $(Y,Ca)(Ba,Ca)_2Cu_3O_{7-\delta}$ compounds shows that pressure-induced charge-transfer alone cannot explain the observed results and an "intrinsic" pressure effect on T_c is included. This term, $dT_{c,\max}/dP$, is assumed to be independent of P and n. Thus, the empirical modified pressure-induced charge-transfer model can be written as

$$T_c(n,P) = T_{c,\max}(n_{\text{optimal}},0) + (dT_{c,\max}/dP)\times P + A\times[(n-n_{\text{optimal}}) + (dn/dP)\times P]^2,$$

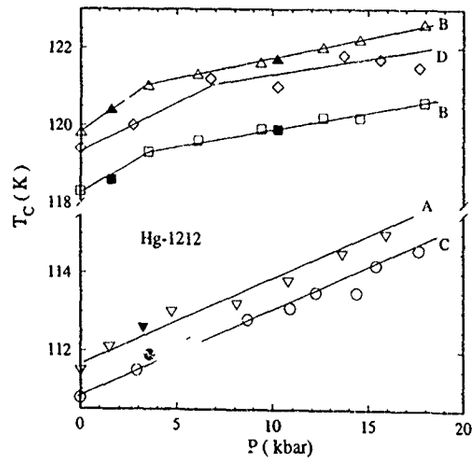

FIG. 2. T_c vs P for Hg-1212. △: T_{co} for sample B, ◇: T_{co} for sample D; □: T_{cm} for sample B, ▽. T_{cm} for sample A; ○· T_{cm} for sample C. Filled symbol obtained on pressure reduction.

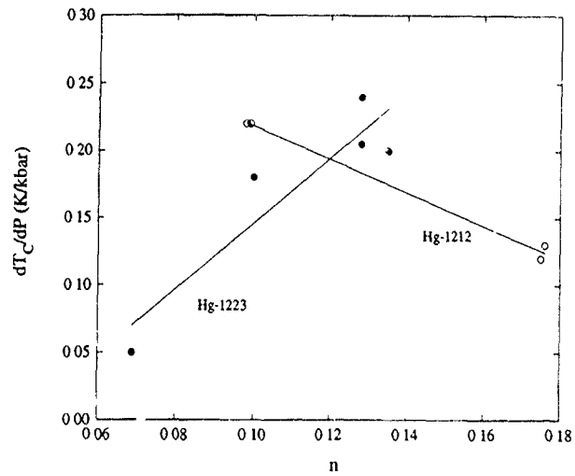

FIG. 4. dT_c/dP vs n for Hg-1212 and Hg-1223.

where A is a negative compound-dependent constant. By ignoring higher order contributions, the pressure effect on T_c becomes

$$dT_c/dP = dT_{c,\max}/dP + 4A \times dn/dP \times (n - n_{\text{optimal}}),$$

which should decrease with n (oxidation), since $dn/dP > 0$ (which has been demonstrated by the negative $d\rho/dP$, positive dR_H/dP;[8] where ρ is normal state resistivity and R_H is the Hall coefficient). However, the average dT_c/dP increases with n in Hg-1223, despite the negative $d\rho/dP$ over the whole P range. This is in direct conflict with the model[2] and suggests that $dT_{c,\max}/dP$ should be P and/or n dependent. The ever increasing dT_c/dP with P after oxidation (cf. Fig. 3) suggests that the T_c of Hg-1223 can be enhanced further by applying pressures up to 500 kbar.[9]

In summary, we investigated the pressure effect on samples of Hg-1212 and Hg-1223 with different oxygen contents. We found that the pressure effect becomes rather nonlinear after oxidation. Although a modified charge-transfer model can explain the pressure effect on Hg-1212, it is in direct conflict with the observation on Hg-1223. The positive dT_c/dP for all the samples suggests that high T_c is optimistic.

The magnetoconductivity of polycrystalline $Bi_2Sr_2Ca_{1-x}Y_xCu_2O_{8+\delta}$, $x=0$, 0.05 and 0.20 samples in the magnetic field of 4 T was measured. The excess conductivity has been analyzed in the light of Aronov–Hikami–Larkin and Bieri–Maki formalisms together with Thompson's correction of the Zeeman term of both theories. The later theory was found within the clean limit to describe the data adequately and yielded the estimate for the phase braking time $\tau_\phi \simeq 1\times10^{-13}$ s. The Maki–Thompson–Zeeman contribution ($\Delta\sigma_{MTZ}$) in these samples is found to be negligible.

The short coherence length coupled with the high transition temperature provide an excellent opportunity to study the rounding of the transition in the oxide superconductors. The fluctuation enhanced conductivity, i.e., excess conductivity ($\Delta\sigma$) in zero field is representable by the Aslamazov–Larkin (AL) and Maki–Thompson (MT) terms.[1] The magnetic field affects the excess conductivity through the orbital angular momentum giving rise to AL-orbital ($\Delta\sigma_{ALO}$) and MT-orbital ($\Delta\sigma_{MTO}$) terms and through the spin angular momentum yielding AL-Zeeman ($\Delta\sigma_{ALZ}$) and MT-Zeeman ($\Delta\sigma_{MTZ}$) terms. Aronov, Hikami, and Larkin[2] (AHL) have derived the expressions for these terms from the standard theory in the dirty limit. However this theory is not applicable to high T_c superconducting (HTSC) materials as they fall within the clean limit with the mean free path $l \geqslant \xi_{ab}(0)$ [$l \simeq 100$ Å and $\xi_{ab}(0) \simeq 15$ Å for $YBa_2Cu_3O_7$ (YBCO)]. Later Bieri and Maki[3] (BM) proposed another theory of $\Delta\sigma(H)$ which was valid for the clean limit but it gave results identical to the AHL theory. Both AL contributions are not sensitive to the mean free path of the electrons. Therefore, their values remain essentially unchanged in both dirty and clean limits. However the MT contribution depends sensitively on l since the vertex renormalization is essentially controlled by l in the clean limit. The expressions obtained by Bieri and Maki[3] in this limit for all the four terms are identical to the AHL expressions with the difference that the terms $\Delta\sigma_{ALZ}$ and $\Delta\sigma_{MTZ}$ had $(\omega_s/4\pi kT)^2$ instead of $(\omega_s/4\pi kT_c)^2$ as their prefactors and δ was defined by $\delta = 1.203[l/\xi_{ab}(0)]\delta_{AHL}$, where δ_{AHL} is given by (Ref. 2) $\delta_{AHL} = 16\xi_c^2(0)kT\tau_\phi/\pi d^2\hbar$. Later it was pointed out by Thompson[4] that both these theories were wrong in treating the Zeeman splitting energy, correction to this leaves the three terms, viz., $\Delta\sigma_{ALO}$, $\Delta\sigma_{MTO}$, and $\Delta\sigma_{ALZ}$ unchanged but modifies the fourth $\Delta\sigma_{MTZ}$.

Experimentally almost all the attention appears to have been focused on YBCO only and to the best of our knowledge no attempt has been made to study the $Bi_2Sr_2CaCu_2O_{8+\delta}$ (BSCCO) system in this light. Earlier Matsuda *et al.*[5] analyzed the magnetoconductivity of YBCO thin films in terms of AHL formalism without Thompson correction. All four contributions were required giving the value of the phase breaking time $\tau_\phi \simeq 10^{-13}$ s at 100 K. However Semba *et al.*[6] found no evidence for the $\Delta\sigma_{MTZ}$ in their data on single crystals of YBCO. They found $\tau_\phi \simeq 5\times10^{-14}$ s which is the shortest time reported so far. Sugawara *et al.*[7] have analyzed their $\Delta\sigma(H)$ data measured on chemical vapor deposition (CVD) films of YBCO in BM theory with Thompson's correction[8] (BMT), and find the $\Delta\sigma_{MTZ}$ term to be essential in both the $\Delta\sigma(H)$ vs ϵ [$=(T-T_c^{mf})/T_c^{mf}$, T_c^{mf} is the mean field transition temperature] as well as $\Delta\sigma(H)$ vs H data. In polycrystalline YBCO Matsuda *et al.*[9] also found vanishing values of $\Delta\sigma_{MTZ}$ using uncorrected AHL expressions. And our recent analysis on similar samples in the light of corrected AHL/BM expressions support these results.[10]

We have measured the magnetoconductivity of polycrystalline $Bi_2Sr_2Ca_{1-x}Y_xCu_2O_{8+\delta}$ samples with $x=0$, 0.05, and 0.20 and find the $\Delta\sigma_{MTZ}$ contribution to be negligible.

The samples were prepared by the matrix precursor method by reacting Bi_2O_3 with a $Sr_2CaCu_2O_8$ precursor in the presence of O_2 at 900–950 °C. All the samples were confirmed to be of single phase by x-ray diffraction (XRD). dc conductivity was measured by the four probe method on bar shaped samples.[1] The current density used was typically 0.1 A/cm^2. Samples were so oriented that the measuring current was perpendicular to the applied field. The sample temperature was measured with a Si diode/CGR thermometer placed in contact with the sample in a copper holder, and was raised at the rate of 2 K/h. The data were taken at the interval of 20 mK within the transition region.

At high temperatures ($T \geqslant 2T_c$) the zero field and the field data coincide for all the samples implying negligible magnetoresistance to be present in the normal state and below T_c^{mf} the transition broadens in the field. A field of 4 T was used because for the higher fields the orbital terms show deviations from the H^2 behavior predicted by the above theories.[2,3] In zero field, a single sharp peak in $d\rho/dT$ is symmetrical about the temperature T_{max} of its maximum, whereas in the field this curve spreads towards lower temperatures. This spread is around 35 K for $x=0$ and increases further with the Y concentration.

We have analyzed the total fluctuation conductivity $\Delta\sigma_f(H) = [\sigma(H,T) - \sigma_n(H,T)]$ where $\sigma_n(H,T) = 1/\rho_n(H,T)$ is the background conductivity. $\Delta\sigma_f(H)$ contains the zero field conductivity (Ref. 11) $\Delta\sigma(0)$ and the modifications produced in it by the magnetic field. BMT-c	1.9	10.4	0.12	5.3	61.2

mation of background conductivity $\sigma_n(H,T)$ have been discussed in detail in Ref. 1.

The experimental data of $\Delta\sigma_f(H,T)$ of $x=0$ was first fitted to the combined expressions of zero field AL and MT terms and field dependent AHL expressions of AL and MT terms with Thompson's correction by taking $\xi_c(0)$, $\xi_{ab}(0)$, and τ_ϕ as the adjustable parameters. τ_ϕ was assumed to vary as $\tau_\phi=\tau_{\phi 0}/T$ where $\tau_{\phi 0}$ is a constant. The values of fitted parameters are shown in Table I. Good agreement can be obtained with $\xi_c(0)=1.9$ Å, $\xi_{ab}(0)=10.0$ Å, and $\tau_\phi=1\times10^{-13}$ s. The value of $\xi_c(0)$ agreed with that obtained from the zero field data.[1] The agreement further improved when BM equations with Thompson's correction were used and the mean free path l was allowed to vary with temperature as $l=l_0/T$ where l_0 is a constant. Here in the clean limit $\xi_c(0)$, $\xi_{ab}(0)$, and $l_0\tau_{\phi 0}$ were taken as the free parameters. $\xi_c(0)$ slightly increased to 2.3 Å and $\xi_{ab}(0)$ decreased to 9.1 Å. We obtained $l_0\tau_{\phi 0}=6.8\times10^{-8}$ Å s. To get an estimate of τ_ϕ from this product, we note that $l=\tau v_F=\tau_0 v_F/T$ (i.e., $l_0=\tau_0 v_F$) where τ is the transport relaxation time and v_F the Fermi velocity of the carriers. The later is estimated as $(0.6-1.6)\times10^7$ cm/s from the relation $\xi_{ab}(0)=\hbar v_F/\pi\Delta$ with the in-plane energy gap parameter given[12] by $2\Delta/kT_c=3.5-8$. Now assuming $\tau_\phi\simeq\tau$ this product yields τ_ϕ (100 K)$\simeq1.3\times10^{-13}$ s for the lowest estimate of v_F, i.e., $v_F=0.6\times10^7$ cm/s. This compares well with the value obtained by Sugawara *et al.*[7] Batlogg,[12] from the resistivity data, has obtained $\tau=\hbar/1.35kT=5.4\times10^{-12}/T$. With $v_F\simeq10^7$ cm/s, this yields $\tau_\phi(100\ K)\simeq5\times10^{-14}$ s from our estimates of $l_0\tau_{\phi 0}$ and the τ_ϕ/τ comes out to be $\simeq2.3$.

BMT[8] have further also assumed $\xi_c(0)$ and $\xi_{ab}(0)$ to be temperature dependent along with l, for both dirty and clean limits. Assuming these temperature variations, values of the parameters obtained are listed in Table I. Both the limits give identical values of $\xi_c(0)$ as 1.8 Å whereas $\xi_{ab}(0)$ works out to be $\simeq9$ Å and $\simeq10$ Å for the dirty and clean limits, respectively, at 100 K. These values agree with those obtained by BMT on single crystals of YBCO. Our analysis yields $\tau_\phi/\tau=0.2$ and $v_F=7\times10^6$ cm/s for the clean limit using the Batlogg's[12] value of τ. This is the clean limit τ and therefore

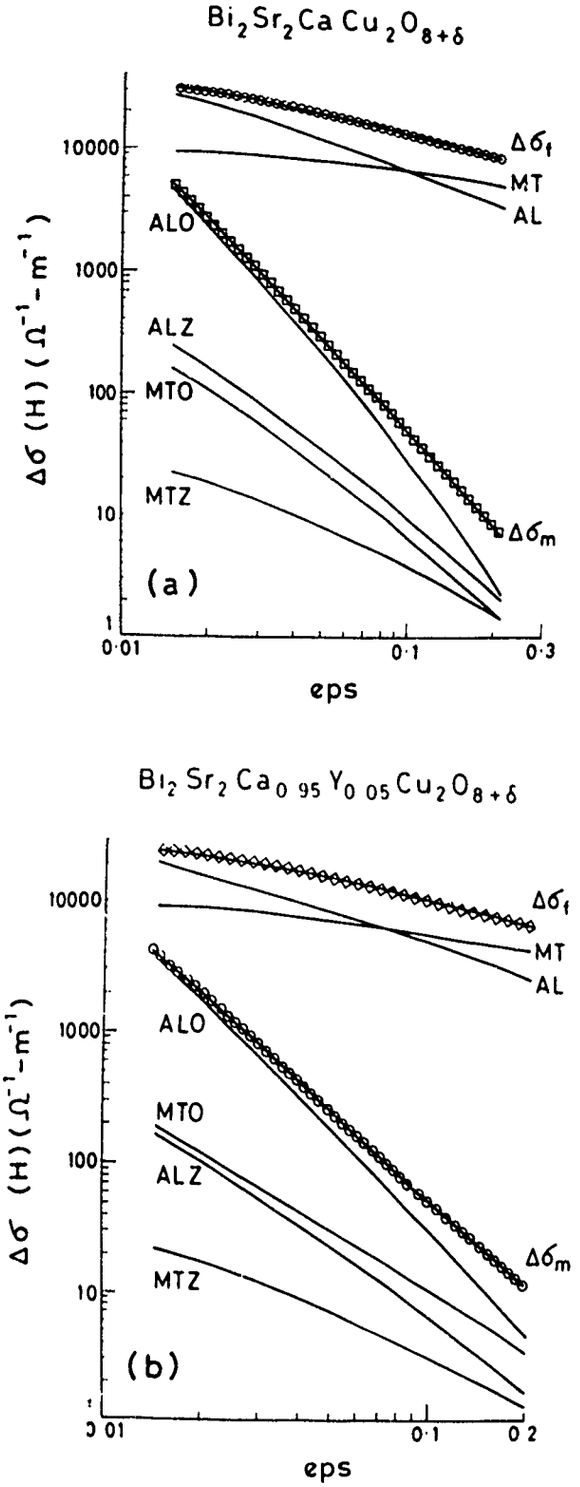

FIG. 1. Fluctuation and magnetoconductivity of BSCCO $x=0$ and 0.05 in (a) and (b). In (a) $\xi_c(0)$ and $\xi_{ab}(0)$ are temperature dependent while in (b) they are constants. Note the change in relative order of ALZ and MTO contributions in (a) and (b). All the four contributions to $\Delta\sigma(H,T)$, i.e., ALO, MTO, ALZ, and MTZ and the excess magnetoconductivity $\Delta\sigma_m$ displayed here, are negative in magnitude.

cannot be used in the dirty limit as has been used conventionally. To estimate τ in the dirty limit we assumed $v_F=1\times10^7$ cm/s. We get $\tau_\phi\simeq1\times10^{-13}$ and τ in this limit$=\tau_d=1.3\times10^{-15}$ s. Thus $\tau_\phi/\tau_d\simeq62$. This ratio is too large. τ_d appears to be too small, its reasonable value should be a smaller fraction of τ. If v_F is reduced further the ratio τ_ϕ/τ also gets reduced but it still remains too high. In the case of AHL τ is also very small. As this theory is valid for the dirty case, l will be $\simeq\xi_{ab}(0)$. With $v_F\simeq10^7$ cm/s this yields $\tau_d\simeq1\times10^{-14}$ s and $\tau_\phi/\tau_d\simeq10$.

Two points are to be noted about this analysis. The data has been fitted over the range $0.01\leqslant\epsilon\leqslant0.2$ and the nonlocal effects have not been included. These effects apparently become visible at $\epsilon\geqslant0.25$ as shown by BMT.

The magnetoconductivity obtained by subtracting $\Delta\sigma_{AL}(0)$ and $\Delta\sigma_{MT}(0)$ from $\Delta\sigma_f(H,T)$ is displayed in Fig. 1(a) along with the calculated values of the four field dependent contributions. $\Delta\sigma_{MTZ}$ has the smallest value over the entire ϵ range, being less than 1% of the total $\Delta\sigma_f(H,T)$. The fit does not deteriorate when the term $\Delta\sigma_{MTZ}$ is dropped altogether. However the rms deviation jumps when the next larger term $\Delta\sigma_{ALZ}$ is dropped. This result is in conformity with our previous conclusion[10] on polycrystalline YBCO (measured at 4 T) and with Semba *et al.*[6] and Matsuda *et al.*[9] who also found $\Delta\sigma_{MTZ}$ to be negligible in their magnetoconductivity of single crystal and polycrystalline YBCO, respectively, measured at 1 T. However Sugawara *et al.*[7] found this term to be present as a substantial fraction of the total magnetoconductivity at 13 T. Since the BMT equations predict each of the four contributions to be proportional to $-H^2$, the relative magnitude of $\Delta\sigma_{MTZ}$, i.e., the ratio $\Delta\sigma_{MTZ}/(\Delta\sigma_{ALO}+\Delta\sigma_{MTO}+\Delta\sigma_{ALZ}+\Delta\sigma_{MTZ})$ will not increase with H and will be a function of ϵ and τ_ϕ only. In actual practice since $\Delta\sigma_{ALO}$ and $\Delta\sigma_{MTO}$ show some saturation at high fields near T_c(at $\epsilon\leqslant0.015$) the ratio may increase at such fields. For the present data the equations predict the ratio to be less than 1% over the entire ϵ range of the data, i.e., for $0.05\leqslant\epsilon\leqslant0.2$, and to remain at negligible levels even when τ_ϕ is increased to $\simeq10^{-13}$ s. The anisotropy ratio $(\Delta\sigma_{MTZ}+\Delta\sigma_{ALZ})/(\Delta\sigma_{ALO}+\Delta\sigma_{MTO}+\Delta\sigma_{ALZ}+\Delta\sigma_{MTZ})$ works out to be 5.6 at $\epsilon=0.05$ and $\Delta\sigma_{MTZ}$ forms 10% of this ratio.

The magnetoconductivity of the $x=0.05$ and 0.20 samples behaves identically. The plot for $x=0.05$ is shown in Fig. 1(b). $\Delta\sigma_{MTZ}$ here is also negligible and the neglect of this term does not alter the fits in any of these samples. Though the AHL theory gives reasonable estimates of τ_ϕ, it underestimates τ thus yielding a very large value for the ratio τ_ϕ/τ. This ratio is similarly overestimated in the BMT dirty limit and underestimated in its clean limit. Only when $\xi_c(0)$ and $\xi_{ab}(0)$ are taken as temperature independent does this theory yield reasonable estimates of τ_ϕ/τ. The values are listed in Table I. All the parameters, viz., τ_ϕ, $\xi_c(0)$ and $\xi_{ab}(0)$, etc., increase systematically with Y concentration. τ_ϕ shows a slight increase with Y doping but still $\Delta\sigma_{MTZ}$ remains negligible. However this increase in τ_ϕ increases the magnitude of the $\Delta\sigma_{MTO}$ relative to those of the other two. Instead of being the smallest term as in the Y-free sample, it over takes $\Delta\sigma_{ALZ}$ and becomes the second largest term.

In summary our analysis of the magnetoconductivity of Y-doped polycrystalline BSCCO suggests the absence of $\Delta\sigma_{MTZ}$ contributions for the fields up to 4 T. The other three terms $\Delta\sigma_{ALO}$, $\Delta\sigma_{MTO}$, and $\Delta\sigma_{ALZ}$ all contribute significantly. Due to the absence of $\Delta\sigma_{MTZ}$ the validity of the Thompson correction could not be verified. Though BMT theory appears to agree with experiments, for a better estimate of τ_ϕ prior knowledge of some of the parameters, $\xi_c(0)$, $\xi_{ab}(0)$, or v_F, will be useful. Data further appear to favor the temperature independent value of $\xi_c(0)$ and $\xi_{ab}(0)$ and discard their functional forms given by the BMT equations.

A new effect called "*ac-current straightening*" has been observed in ceramic (Bi,Pb)-2223 slabs carrying ac current $I_{dc}+I_{ac}\cos(\omega t)$. The current-voltage ($I$-$V$) characteristics of the ceramic were measured at 77 K at frequencies ranging from 50 to 20 000 Hz. A spectrum analyzer showed a series of high harmonics in the voltage signal as well as a constant voltage drop. The full set of experimental data has been explained theoretically using the Bean–Kim critical state model with a magnetic field dependent critical current $j_c(H)=j_c(0)/(1+H/H_0)$. A low transport ac current gives a voltage linearly proportional to the frequency and quadratically proportional to the ac-current amplitude I_{ac}. It consists of odd harmonics only. If a bias dc current is switched on, then even harmonics and a dc-voltage drop appear. Their amplitudes are proportional to the small parameter I_{ac}/cH_0 and depend on the I_{dc}/I_{ac} ratio.

One of the main features of high-T_c superconductors is the very wide interval of magnetic field and temperature in the H-T diagram between the two critical fields $H_{c1}(T)$ and $H_{c2}(T)$ conditioned by extremely small coherence length. Due to this fact and the great anisotropy of the samples, magnetic vortices cause the strong nonlinearity of magnetic and transport properties in the mixed state for high-T_c superconductors even at very low magnetic fields and current densities. Strong magnetic field dependence of susceptibility and aharmonic diamagnetic response manifest this behavior (see, for example, Ref. 1). In the present article we report experimental observations and a theoretical explanation for a new effect in current transport properties. Pinning of vortices results in odd harmonics in the voltage response for sinusoidal ac currents. Field dependence of the critical current causes even harmonics and a dc-voltage drop if a bias dc-transport current or a dc-magnetic field violate the symmetry $t\rightarrow -t$.

Bulk samples of (Pb,Bi)-2223 were prepared by sintering a commercial 2212+oxides precursor powder, regrinding and pressing it into nominally 10 mm wide bars. dc-testing lead to the conclusion that the critical current is limited by the magnitude of the magnetic self-field at the surface of the bar.[2] A dc-voltage signal was detected when testing using ac+dc currents.[3] The frequency dependence of the effect was examined by using an audio amplifier to increase the current from a frequency generator. Necking and a reduction in the size of the specimens were done in some cases to reduce the transport current required to reach the critical magnitude. A four point probe test circuitry was used with a HP 3478A microvolt multimeter to detect the dc voltage across the center contacts. Additional details of the nature of the voltage signals were observed after amplification with a high gain operational amplifier and a storage oscilloscope and the harmonics were found using a HP 3580A spectrum analyzer.

A pure sinusoidal ac current gives a sinusoidal voltage signal from the voltage contacts until the transport current exceeds the dc critical current magnitude I_c. Far above I_c the shape of the voltage signal wave form changes to a more triangular shape due to the odd harmonics in the voltage signal. If a dc offset current I_{dc} is added, then asymmetry can be observed in the $V(t)$ curve as evidence of even harmonic frequencies (Fig. 1, harmonics above and below I_c). Another effect is a dc offset, so that the curve progressively shifts away from the zero axis (on the oscilloscope) as the current is increased further. The dc voltage observed on a multimeter for a dc offset current, is seen to primarily depend on a shift of the voltage curve from the zero axis, since the deformation of the wave form is not as large (Fig. 2). The transition for ac plus dc current testing occurs at approximately the same total current as for dc alone, when using the rms ac current and if $I_{dc}\geq I_{ac}$. This would indicate a common mechanism generating the voltage signals. To examine for frequency dependence in the effect, the frequency of the ac current was varied in the audio frequency range of 50–20 000 Hz by the use of an audio power amplifier. Visible changes in the I-V characteristics were not observed. A VOM was used to measure the critical current at the transition for a triangle, sine, and square wave input. The resistive transition occurred first for the triangle wave, then the sine, and last for the square wave. The VOM uses a fixed resistor and a constant to give the expected current, rather than measuring the voltage and current and the phase angle as in an ac watt meter. Therefore, the ratio of the peak voltage to power is lower for the same current for a square wave input than for a triangular wave form, and the transition sequence follows a decreasing ratio.

We use the critical state model[4] to calculate the distributions of local magnetic field h and current in an infinite superconducting slab (Fig. 3) carrying a transport current $I_{tr}(t)=I_{dc}+I_{ac}\cos(\omega t)$ (the magnetic susceptibility for samples carrying dc+ac transport current has been experimentally studied in Ref. 5). Kim's expression

$$j_c(h)=\frac{j_c(0)}{1+(|h|/H_0)} \tag{1}$$

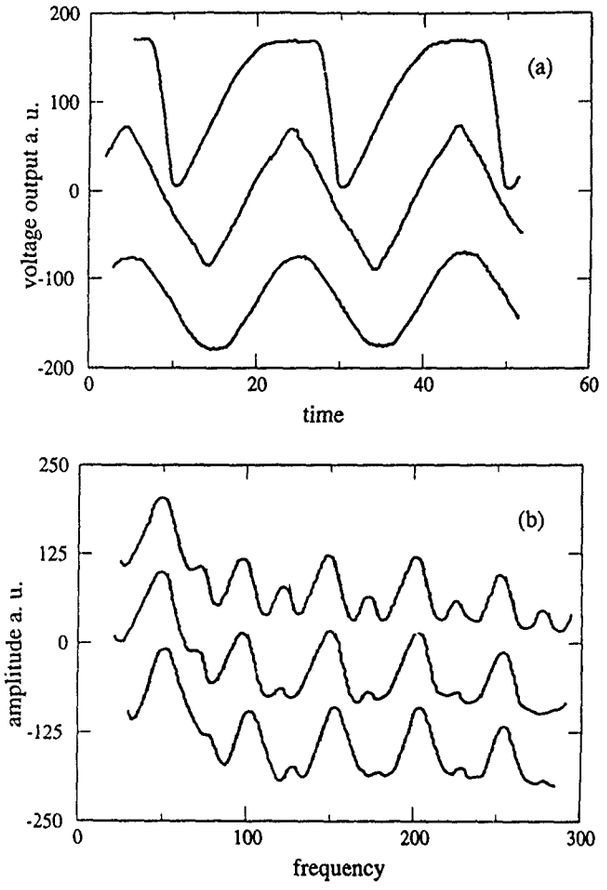

FIG. 1. $V(t)$ for 50 Hz ac-transport currents as a function of time (ms) and the associated harmonic frequencies present (plotted as log I vs frequency ω). The lower curve in (a) is for $I=2.85$ A rms and shows mostly odd harmonics in the superconducting state. Increasing the current to $I=3.51$ A rms, middle curve in (a), distorts the wave form due to flux penetration but symmetry is maintained. A dc-bias current of 0.6 A dc to the middle curves case gives an asymmetric wave form and increases the even harmonics upper curve. In (b) the associated harmonic frequencies to the curves in (a) are shown.

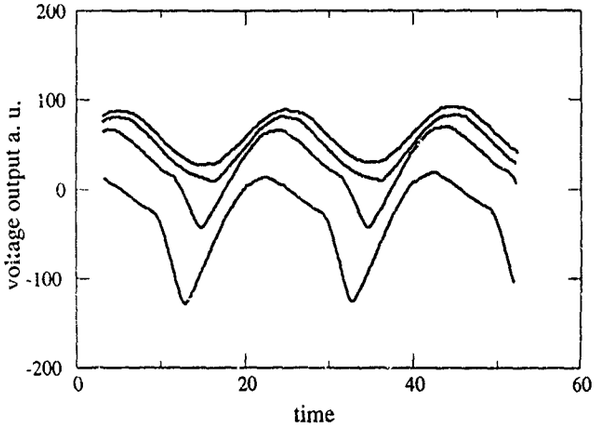

FIG. 2. $V(t)$ wave form for increasing 50 Hz ac currents, while holding I_{dc} nearly constant at 0.9 A Sinusoidal wave form symmetry is gradually lost as I_{ac} is increased in steps 4.04 A (upper curve), 4.51 A, 5.04 A, and finally 5.30 A (rms)

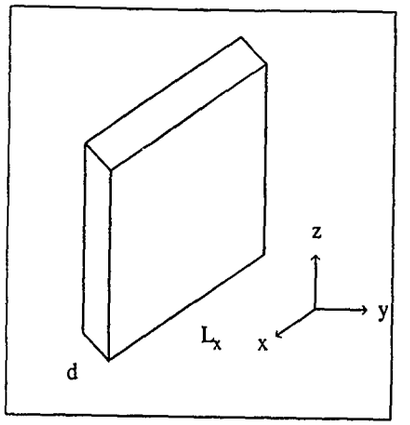

FIG. 3. Experimental setup showing the superconducting slab. The current is driven in the z direction.

is used to define the field dependence of the critical current. Here the parameter H_0 characterizes the reduction of the critical current by magnetic field, and $j_c(0)$ is a function of temperature. Maxwell's equation

$$\frac{\partial h_x}{\partial y}=\pm\frac{4\pi}{c}j_c(h) \tag{2}$$

is solved with a standard boundary condition

$$h_x(d/2)=-(2\pi/c)I_{tr}(t). \tag{3}$$

Signs $\pm$ in Eq. (2) depend on the time-dependent phase of the transport current, and d is the slab thickness. Here and later on we use the linear density of transport current $I=J/L_x$, normalized to the unit of slab width L_x.

The quasistatic solutions of Eq. (2) may be classified for three different cases. The first is a *critical state* realized for low transport currents

$$I_{tr}\leqslant(cH_0/2\pi)[\sqrt{1+[4\pi dj_c(0)/cH_0]}-1]. \tag{4}$$

In this case magnetic field and supercurrents exist near the slab surface only. If the inequality (4) transforms to strict equality, then the magnetic field reaches the center of the slab. Higher transport currents give

$$(cH_0/2\pi)[\sqrt{1+[4\pi dj_c(0)/cH_0]}-1]\leqslant I_{tr}\leqslant j_c(0)d \tag{5}$$

for the *intermediate state*. In this case the supercurrent density is not enough to support the total transport current in the slab. The slab interior is occupied by supercurrent, as before, but near the slab surface the normal state occurs with a uniform normal current density higher than $j_c(h)$. If the transport current continues to increase, then the boundary between critical and normal states reaches the center of a sample and

$$I_{tr}\geqslant j_c(0)d, \tag{6}$$

which is the *normal* state in the entire slab.

We present here the final results in the limiting case using the *critical state* (4), and a low bias dc component in the transport current

$$I_{dc}\leqslant I_{ac},$$
$$2\pi|I_{tr}|/cH_0\leqslant 1. \tag{7}$$

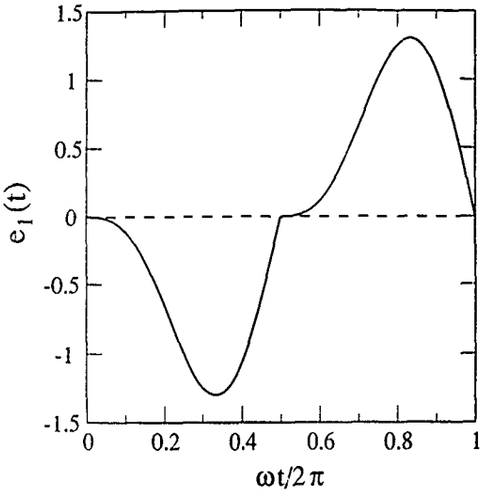

FIG. 4. Graph of the function $e_1(t)$ in Eq (8). The dashed line represents the zero level.

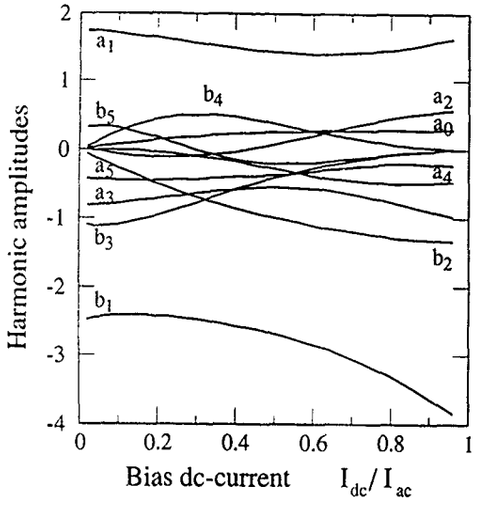

FIG. 5. The Fourier amplitudes a_0-a_5 and b_1-b_5 used in the evaluation of $e_2(t)$ in Eq. (8). $e_2(t)$ describes the additional voltage caused by the field dependence of critical current vs bias dc current.

For these conditions the electric field into the slab may be presented as a sum of two terms

$$E(t)=\frac{\pi I_{ac}^2\omega}{4c^2 j_c(0)}\left[e_1(t)+\frac{\pi I_{ac}}{cH_0}e_2(t)\right],$$

$$e_1(t)=-\sin(\omega t)+|\sin(\omega t)|\cos(\omega t)$$

$$=-\sin(\omega t)+\frac{4}{\pi}\sum_{k=0}^{\infty}\frac{\cos[(2k+1)\omega t]}{4-(2k+1)^2}, \qquad (8)$$

$$e_2(t)=a_0+\sum_{k=1}^{\infty}[a_k\cos(k\omega t)+b_k\sin(k\omega t)],$$

where $e_1(t)$ is the main ac-voltage signal. The shape of the function is presented in Fig. 4. As can be seen from Eq. (8) it contains odd harmonics only. And an additional term $e_2(t)$ appears because of the dependence of the critical current on the local magnetic field.[1] Its contribution to $E(t)$ in Eq. (8) is small, since the parameter $(2\pi|I_{tr}|)/(cH_0)\ll 1$ [Eq. (7)]. It contains both odd and even harmonics. The dependences of the Fourier amplitudes a_0, a_k, and b_k on the parameter I_{dc}/I_{ac} are presented in Fig. 5. All even harmonic amplitudes go to zero with $I_{dc}\to 0$. The item a_0 in Eq. (8) corresponds to the "straightened voltage drop." It appears only when a bias dc current I_{dc} appears. It is remarkable that the straightened voltage magnitude in $E(t)$ is linearly proportional to frequency and quadratically in the low (and cubically in the high) ratio of the I_{dc}/I_{ac} case for the ac-current amplitude, since no frequency dependence was seen experimentally.

In summary, a new effect called ac-current straightening has been observed experimentally and explained theoretically. Strong nonlinear dependence of shielding supercurrents from external magnetic fields causes the occurrence of high harmonics in the voltage signal. The field dependence of the critical current leads to stratification of the sample into a critical state interior and a normal state exterior. Even harmonics and dc-voltage drop appear for bias dc-transport currents or dc-magnetic fields.

The decay of magnetization with time is recorded for a quench-melt-growth processed $YBa_2Cu_3O_{7-x}$ sample. The vortex-glass and collective pinning theories fit the data quite well over all time regimes with an exponent, μ, value of 0.78. The normalized logarithmic magnetic relaxation rate, S, attains a plateau value of 0.05, considerably higher than a variety of samples which fall within a universal plateau curve.

INTRODUCTION

The understanding of the pinning mechanism is essential for the improvement of the critical current in high-temperature superconductors. A key component that determines the critical current density J_c and the relaxation rate of the magnetization S is the pinning energy $U(J)$. Measurement of the magnetic relaxation $M(t)$ has been one of the most popular means of investigating pinning phenomena in high-temperature superconductors. The relaxation of magnetization is usually interpreted within the framework of the thermally activated flux flow (TAFF) over an average energy barrier U. In the simplified model, first proposed by Anderson,[1,2] U is assumed to vary linearly with the current density J. In general, however, a number of different competing mechanisms govern the interaction of flux lines and defects.[3–7]

A number of articles have proposed varying forms of $U(J)$, resulting in magnetization relaxation with time that obeys a logarithmic law,[2] a power law,[4] or an exponential law.[5] These analytical expressions can describe well the experimental data over a limited time window. Our various YBCO samples show dependencies of $M[(\ln t)]$ that deviate from straight lines at long times. More complex models, such as the collective pinning (CP) theory of Fiegel'man *et al.*[8,9] and the vortex-glass (VG) theory of Fisher *et al.*,[10] predict an interpolation formula of the form

$$M(t)=M(0)[1+(\mu kT/U_0)\ln(t/t_0)]^{-1/\mu}. \quad (1)$$

Phenomenologically, this implies a potential barrier of the form

$$U(J)=(U_0/\mu)[(J_{c0}/J)^{\mu}-1], \quad (2)$$

where U_0 and J_{c0} are, respectively, temperature dependent barrier height and critical current density in the absence of flux creep. The value of the exponent μ is controversial. Its value has been reported to vary from 0.2 to 2.5, and others have even reported it to be dependent on temperature and applied field.[11–15]

In the study reported here, we have investigated the pinning mechanism by measuring the kinetics of magnetization in a crystalline sample of $YBa_2Cu_3O_{7-x}$ (YBCO or 123) prepared by the quench-melt-growth (QMG) process.[16] The sample is similar to one whose relaxation rates are described elsewhere.[17] The QMG sample was produced by melting a solid-state sintered YBCO superconductor precursor powder at 1450 °C, holding for 5 min before quenching the liquid onto a copper plate. The resultant glass was rapidly reheated to 1150 °C and cooled to 1000 °C at 200 °C/h. The samples were then cooled at a very slow rate (1 °C/h) to 940 °C in order to go slowly through the peritectic temperature. Below the peritectic temperature, the reaction Y_2BaCuO_5 (211)+liq =123 occurs, forming the superconducting YBCO phase. The main difference between the present sample and the earlier one[16] is that better temperature control was achieved during processing of the present sample, and the microstructures of the two samples are very different. The earlier sample contained areas of inclusion-free single crystal 123, but containing parallel arrays of microcracks. During the rapid reheating of the earlier sample, there were temperature oscillations above 1150 °C by as much as 25 °C. The oscillations occurred during the first minute of reheating. The higher temperature may have caused dissolution of the 211 particles in the melt. In contrast, for the present sample the temperature did not exceed 1150 °C and although it contains porous regions, 211 and CuO inclusions, it has inclusion-free single crystal 123 regions which are not microcracked.

EXPERIMENTAL METHODS

Measurements of the isothermal magnetization M were carried out for a set of temperatures T between 10 and 70 K using superconducting quantum interference device (SQUID) magnetometry. The samples were first cooled to the measuring temperature in zero magnetic field (ZFC). A magnetic field of 0.4 T was then applied, and the magnetization, $M(t)$, was recorded as a function of time. Measurements of the decay of the remanent magnetization M_{rem} were also carried out, but are not reported in this article. The results for M_{rem} were similar to those obtained for the ZFC procedure.

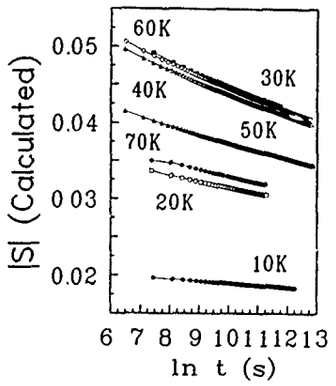

FIG. 3. The time variation of the normalized logarithmic rate, $|S|$, for various temperatures.

RESULTS AND DISCUSSION

A typical result of the decay of the magnetization M versus time at $T=40$ K and $H=0.4$ T is displayed in Fig. 1. This curve (and the curves at all the other temperatures) shows deviations from a logarithmic law or an exponential law at the long times ($1.4 \leq t \leq 400$ ks). The normalized logarithmic rate $\mathbf{S}=|d[\ln M]/d[\ln t]|$ versus temperature is shown in Fig. 2, for a time of $\cong 1.4$ h after the field was turned on. The time variation of $|\mathbf{S}|$ is shown in Fig. 3. The sample is small enough for complete field penetration (verified by Meissner measurements) and the values of **S** are a suitable measure to compare the pinning properties of different crystals. For most YBCO samples, there is a universal curve in which $|\mathbf{S}|$ values attain a plateau within the range of 0.022 to 0.038 (shaded area of Fig. 2) for the temperature interval ≈ 30–60 K.[18] Crystals containing only small defects show a low and constant **S** with temperature. By comparison, our QMG sample has a plateau with a high value of $S \approx 0.05$ which lies outside the universal plateau curve. A high value of S is usually associated with the existence of extended defects.[19]

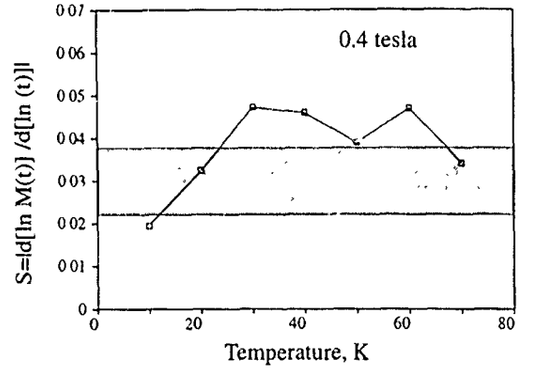

FIG 2. Normalized logarithmic rate $S=|d[\ln(M)]/d[\ln(t)]|$ vs temperature, evaluated at $t=5$ ks The shaded area represents data obtained from Refs. 17 and 18

The VG and CP models fit the data quite well over the entire measured time range. Results obtained by fitting the data to Eq. (1) (see Fig. 1) indicate that μ lies between 0.7 to 0.9 in the temperature interval 10–70 K, similar to the values observed by Ren and de Groot[14] for a flux-grown YBCO single crystal which is described as being heavily twinned and containing many defects. In contrast, for highly proton-irradiated YBCO single crystals,[11] and for melt-textured samples of YBCO Ref. 20, μ was found to be 0.5 at $T=10$ K, reach a peak of 1.4 at $T=30$ K, and then drop back to a low value at $T=60$ K.

The VG theory of Fisher *et al.* predicts that μ is a universal exponent less than 1. The CP model of Fiegel'man *et al.* assumes weak pinning and proposes three different regimes of current density J and thus three different values of μ depending on the flux bundle size. In the three dimensional case, $\mu=1/7$ for the high current region, $\mu=3/2$ for intermediate J, and $\mu=7/9$ for much lower J values. The values of μ obtained for our QMG sample have an average value near 7/9 for $10 \leq T \leq 70$. Assigning a μ value from 0.7 to 0.9 does not significantly affect the goodness of fit (correlation coefficient $r^2 \approx 0.998$) for any of the temperatures. We therefore analyzed all of our data for a fixed value of 7/9. This value of μ is consistent with the VG and CP models associated with large vortex bundles. QMG samples can be considered as nearly bulk superconductors with weak links.[10] The pinning energy, U_0, obtained from our fits is approximately constant at 0.043 eV for the temperature interval 10 to 30 K, and rises to over 0.1 eV at 70 K. This behavior is different than that found[3,21] for single crystals where U_0 continued to decrease as the temperature was lowered below 30 K.

In summary, we have measured the magnetic relaxation of a QMG-processed YBCO crystal. We have found that CP and VG models fit our data quite well. The value of μ is controversial, with the different μ values found in the literature appearing to depend on the technique of measurement and method of sample preparation. The data obtained here over a wide temperature range from either $M(t)$ and $M_{\text{rem}}(t)$ is in agreement with $\mu=7/9$ for our sample, as predicted by the collective pinning theory, and is consistent with the VG model for large vortex bundles.

We report detailed magnetization studies on a single crystal $Nd_{1.85}Ce_{0.15}CuO_{4-\delta}$ superconductor in the magnetic field parallel to the c-axis direction. Two characteristic peaks are observed in the magnetization data, corresponding to surface barriers and two-dimensional (2-D) collective pinnings. The critical currents corresponding to the maximum and minimum widths in the hysteresis loops increases with decreasing temperature exponentially. We propose that the fishtail magnetization in this compound is due to the presence of a surface barrier and the pinning of collective 2-D vortices. The initial peak in magnetization is due to the presence of Bean–Livingston surface barriers and the larger peak in M at higher H corresponds to 2-D pinning.

The study of vortex pinning in the high T_c cuprate systems is of great interest in terms of both fundamental physics involved and application of these materials as current-carrying devices. One of the many interesting features observed in these compounds is the so-called fishtail magnetization.[1] The critical current defined as the width of a hysteresis loop at a given temperature increases with increasing field. This effect has been observed in several high T_c materials, including YBCO, BISCO, and a Tl compound.[1-3] However, the mechanism for this behavior is still controversial.

In this work, we report extensive magnetic measurements performed on a low T_c single crystal $Nd_{1.85}Ce_{0.15}CuO_{4-\delta}$ superconductor. The magnetization (M) measured as a function of field shows a similar fishtail characteristics in $H\|c$-axis direction. At high temperatures, M is nearly zero for a certain range of fields in the descending branch of a hysteresis loop. At low temperatures, pinning becomes increasingly important. The critical currents defined at the minimum and maximum widths of the magnetization loop can be well fit with an exponential temperature dependence, $J_c = J_0 \exp(-T/T_0)$. We propose that the anomalous fishtail magnetization is due to surface barriers and pinning of the collective two-dimensional (2-D) vortices.

Single crystals of $Nd_{1.85}Ce_{0.15}CuO_{4-\delta}$ are grown using a directional solidification technique.[4] Several crystals are used in the measurement, with average dimensions of $1\times1\times0.02$ mm. Extensive measurements were made on one crystal with a T_c of 21 K. The magnetic transition width measured at 1 G with zero-field cooling is about 1 K. Measurements are performed using a Quantum Design magnetometer with low field options. After de-Gaussing and magnet resetting (quenching), the remanent field is typically 5–10 mG. Measurements reported here are for the $H\|c$-axis configuration.

Shown in Fig. 1 are magnetic hysteresis loops taken at constant temperatures, $T=17$, 13, and 7 K, respectively. The overall shapes are similar to each other, but some differences are clearly visible. At $T=17$ K, shown in Fig. 1(a), the magnetization loop forms a complete fishtail. Three characteristic regimes are clearly observed in the field ascending branch. In the first regime, the magnetization decreases linearly with the field initially (the Meissner state); in the second regime, M increases sharply toward zero from the Meissner state and is followed by an almost constant magnetization for 50 G$<H<$100 G; in the third regime, M decreases again with increasing H, followed by an eventual increase to almost zero with an increasing field. In the field descending branch, three field ranges with almost-mirror-imaged magnetization are observed. However, in the corresponding second regime, the magnetization is almost zero, rather than a constant, as seen in the field increasing direction. At low field, the magnetization increases monotonically with the decreasing field.

At a lower temperature, $T=13$ K, as shown in Fig. 1(b), the magnetization curve is somewhat different from that of 17 K. The maximum sweeping field is increased to 1 kG. The relatively sharp peak in the third regime in Fig. 1(a) is replaced by a broader $M(H)$ dependence at this temperature. The magnetization in the second regime in the field descending branch remains close to zero, followed by increasing M at a lower field. At very low temperature $T=7$ K, shown in Fig. 1(c), the differences are more pronounced. The magnetization at field up to 2 kG is very broad. In the descending branch, the minimum M is finite rather than close to zero.

To quantify the anomalous field dependence of the magnetization, we define several characteristic parameters. For each hysteresis loop, there are two well-defined critical currents. One critical current J_{max} corresponds to the maximum width at H_{max} in the third regime. The other J_{min} can be defined, corresponding to the minimum width in the second regime. The critical current can be obtained by using the standard expression $J=\Delta M/(2r)$ where $\Delta M=|M_-(H)-M_+(H)|$ and r is the effective radius of the specimen. In the following discussion, we will use $J\propto\Delta M$ and obtain the temperature dependence of J from ΔM directly. The temperature dependence of these two widths are plotted in Fig. 2. The solid lines are fits to the expression of $J=J_0\exp(-T/T_0)$, where J_0 is the zero temperature critical current and $1/T_0$ is the slope of the fit. The values obtained for T_0 are 4 and 2 K for maximum and minimum width, respectively. The zero temperature critical values are the

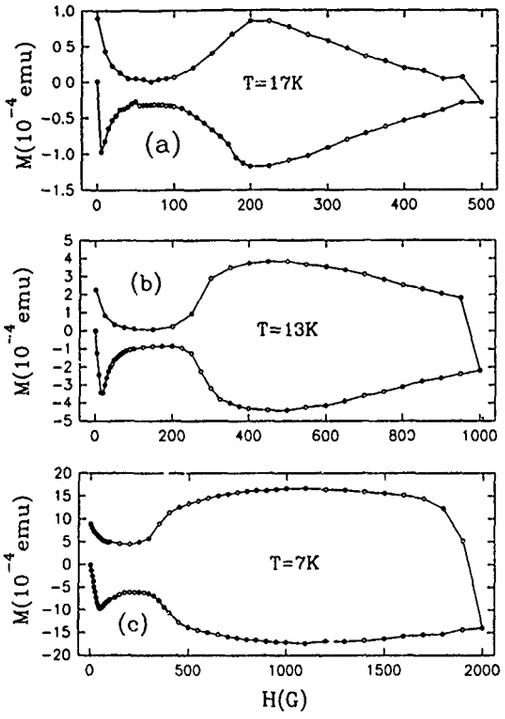

FIG. 1. Magnetization hysteresis loop at (a) $T=17$ K; (b) $T=13$ K, and (c) $T=7$ K in the $H\|c$-axis configuration.

same within the experimental errors. The inset shows the temperature dependence of the maximum peak field. The solid line is a fit to $\ln H_{max}=\ln H_0-T/T_1$, with $H_0=3$ kG and $T_1=7$ K.

The crossover from the minimum to maximum magnetization can be characterized by a crossover field H_x when M is in the middle of M_{min} and M_{max}. The data is very close to each other in both branches. The temperature dependence of H_x is plotted in Fig. 3. At high temperature, H_x increases with decreasing T; at lower temperatures, H_x tends to saturate. The solid line is a two-variable fit to $H_x=H_x(0)[1-(T/T_x)^2]$. The fit gives a $H_x(0)=440$ G and $T_x=21$ K, which is exactly the same as the T_c determined from magnetic and transport measurements. The same T_x is obtained from a linear extrapolation of the high temperature data.

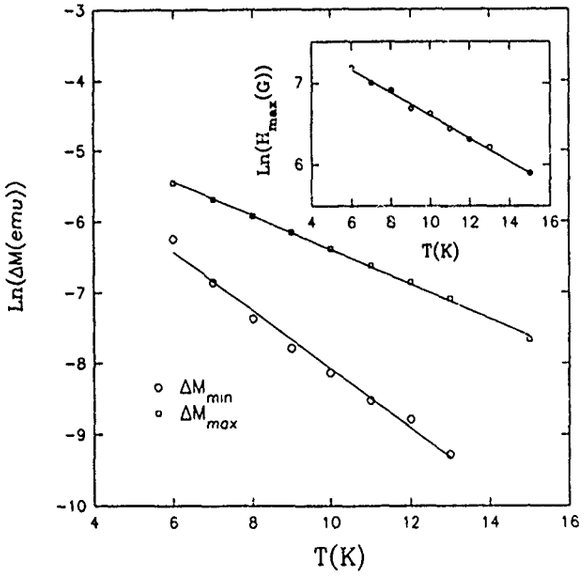

FIG 2. $\ln \Delta M$ as a function of temperature for both ΔM_{max} and ΔM_{min} The lines are fits to $\ln \Delta M=\ln \Delta M_0-T/T_0$ The inset is a plot of $\ln H_{max}$ vs T and the line is a fit to $\ln H_{max}=\ln H_0-T/T_1$

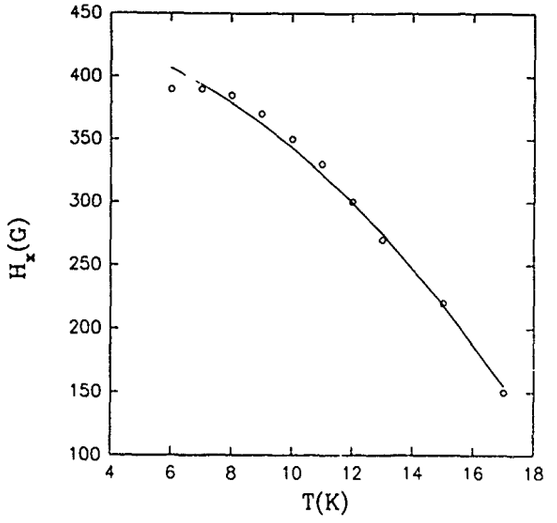

FIG. 3. H_x as a function of temperature. The solid line is a fit to $H_x(T)=H_x(0)[1-(T/T_x)^2]$

The exponential temperature dependence of J is of interest here. The result is consistent with a general collective pinning theory, with the current near its critical state.[5,6] The theory predicts a nonlinear logarithmic time decay of the current density, $j(t)=j_c[1+(\mu T/U_c)\ln(1+t/t_0)]^{-1/\mu}$, where j_c is the zero temperature critical current, U_c is the barrier height, t is the experimental measuring time, and $1/t_0$ is a characteristic frequency. In a typical SQUID measurement, $t=100$ s and $t/t_0\sim10^{10}$. In the single vortex pinning regime, $1/\mu=7$ and $j(t)\simeq j_c\exp(-T/T_0)$, with $T_0\simeq U_c/\ln(t/t_0)$. The exponential dependence is only expected when $j\simeq j_c$. If $j\ll j_c$, the current density has a power-law dependence on temperature, $j(t)\sim j_c[(T/U_c)\ln(t/t_0)]^{-1/\mu}$. We have also tried to fit the critical currents with the power-law dependence; we obtain the exponent $1/\mu$ to be 2 and 3.8 for J_{max} and J_{min}, respectively. However, it is noticed that power-law fit is not as good as that of $\exp(-T/T_0)$.

The collective pinning theory predicts $1/\mu=7$ in the single vortex regime; $\frac{2}{3}$ in the small vortex bundle regime; and $\frac{5}{7}$ in the large vortex regime. It has been proposed recently that the fishtail magnetization is due to the crossover of different pinning regimes.[3] The small M is due to the fast relaxation of single vortices, and large M is due to slow relaxation in the vortex bundle regimes. However, our data clearly indicate lack of correspondence in the exponents $1/\mu$ with the theory. The discrepancy suggests the inadequacy of

applying the model to explain the fishtail shape of magnetization.

The anomalous magnetization can also be derived from a model where the order parameter is reduced substantially at the high field. For example, a region of lower T_c phase can become a strong pinning site once the external field is of order of H_{c2} of that low T_c phase. This can be realized in the YBCO system, where T_c depends strongly on local oxygen stoichiometry. In the low T_c $Nd_{1.85}Ce_{0.15}CuO_{4-\delta}$ compound, T_c does not change appreciably with oxygen content. The local T_c fluctuation model is not appropriate here. This picture is supported by the temperature dependence of the crossover field H_x. If the large peak at high field were due to another lower T_c phase, H_x should be of order of H_{c2}. The temperature dependence of H_x would determine the T_c of this phase. In this case, the fitted T_x being exactly the same as that of the bulk T_c indicates the absence of spurious low T_c structures in this crystal. The temperature dependence of peak field H_{max} is in sharp contrast with the "lattice matching" model, where a peak in M occurs when the vortex density is matched with that of defects. However, in this model the peak field should not change with temperature. The exponential T dependence of H_{max} excludes the lattice matching effect.

We propose that the fishtail magnetization is a result of surface barriers and the pinning of correlated 2-D pancakes. The effects of surface barriers have been considered by Chikomoto and Kopylov earlier.[1,2] The difference between this model and the previous model is that we believe the 2-D nature is very important here. The minimum magnetization in the second regime is due to the combination of surface barriers and fast relaxation of single vortex lines. The increasing magnetization with increasing field is due to the slow relaxation and large pinnings of correlated 2-D vortices.

The presence of surface barrier is evident from high temperature hysteresis loop measurements.[7] The rapid decrease in magnetization in the second regime in the H-ascending direction is consistent with a surface barrier model, where $4\pi M = H - \sqrt{H^2 - H_p^2}$ for $H > H_p$.[8,9] At low T, finite pinning has to be considered to evaluate M. The penetration field H_p increases with decreasing T. The data can be fit with $H_p = H_0 \exp(-T/T_0)$. The result implies that the magnetic penetration is in the form of 2-D pancakes rather than 3-D flux lines. At small field, vortices penetrate the surface barriers in the form of 2-D pancakes. The Josephson and magnetic interaction align the pancakes in different planes once they are inside. Magnetic relaxation is determined by the combination of surface barriers and single vortex line pinning. At high field, the collective pinning lengths in the plane L_{ab} increases with field. If L_{ab} is greater than the Josephson length, the motion of vortices will be dominated by 2-D collective pinnings. The collective pinning will increase the number of pinning centers, thus, the pinning energy and the effective critical current. Measurements of magnetic relaxation as a function of field at a given temperature confirms the different relaxation mechanisms at different fields.[7] We attribute the rising of magnetization at high field to large collective pinning of 2-D vortices and their slow relaxation from a critical state.

In summary, we have reported detailed magnetization studies on a single crystal $Nd_{1.85}Ce_{0.15}CuO_{4-\delta}$ superconductor. The magnetization in the H parallel to c direction shows the anomalous fishtail field dependence. The temperature dependence of characteristic critical currents J_{min}, J_{max}, and the crossover field H_x rules against the 3-D collective pinning model, as well as the oxygen deficiency model. We suggest that the fishtail magnetization is due to the combined effect of surface barriers and collective pinning of 2-D vortices.

On vector generalization of the critical state model for superconducting hysteresis

I. D. Mayergoyz
Department of Electrical Engineering and Institute for Advanced Computer Studies, University of Maryland, College Park, Maryland 20742

The critical state model for superconducting hysteresis is based on an analytical study of the penetration of electromagnetic fields into hard superconductors. In the literature, this study has been carried out for linear and circular polarizations of electromagnetic fields. In the paper, the attempt is made to extend this study to arbitrary electromagnetic field polarizations, which can be treated as perturbations of circular polarizations. Another distinct feature of our work is that this extension is carried out for gradual resistive transitions described by the "power law."

Most of the literature on the critical state model is concerned with scalar superconducting hysteresis. This is because the study of vector hysteresis requires the investigation of penetration of electromagnetic fields into superconductors for the case when these fields are not *linearly* polarized. This is a very difficult analytical problem that requires the solution of coupled nonlinear partial differential equations. This problem has been solved only for *circular* polarization in the case of ideal (sharp) resistive transition,[1] as well as in the case of gradual resistive transition[2] described by the "power law."

In this paper, we consider vectorial polarizations of electromagnetic fields that can be treated as perturbations of circular polarizations. We also consider gradual resistive transitions that are usually described by the following "power law:"

$$E=(J/k)^n \quad (n>1). \tag{1}$$

Here E is an electric field, J is an electric current density, and k is some parameter that coordinates the dimensions of both sides in Eq. (1).

In the vectorial form, the power law can be written as follows:

$$J_x=k(\sqrt{E_x^2+E_y^2})^{1/n-1}E_x, \quad J_y=k(\sqrt{E_x^2+E_y^2})^{1/n-1}E_y. \tag{2}$$

The exponent "n" is a measure of the sharpness of the resistive transition and it may vary in the range 4–1000. At first, the power law was regarded only as an empirical description of the resistive transition. Recently, there has been a considerable research effort to theoretically justify the power law. The related discussion can be found in Refs. 3–5. In this paper, the power law is used as a constitutive equation for hard superconductors.

To start the discussion, consider a plane electromagnetic wave penetrating superconducting half-space $z>0$. The magnetic field on the boundary of this half-space is specified as follows:

$$\begin{aligned} H_x(0,t)&=H_m[\cos(\omega t+\gamma)+\epsilon f_x(t)],\\ H_y(0,t)&=H_m[\sin(\omega t+\gamma)+\epsilon f_y(t)], \end{aligned} \tag{3}$$

where ϵ is some small parameter, while $f_x(t)$ and $f_y(t)$ are given periodic functions of time. It is apparent that this plane wave can be construed as a perturbation of the circularly polarized plane wave. By using the Maxwell equations, we find that the distribution of electric field in half-space $z>0$ is governed by the following coupled nonlinear partial differential equations:

$$\frac{\partial^2 E_x}{\partial z^2}=\mu_0\frac{\partial J_x(E_x,E_y)}{\partial t}, \quad \frac{\partial^2 E_y}{\partial z^2}=\mu_0\frac{\partial J_y(E_x,E_y)}{\partial t}, \tag{4}$$

subject to the boundary conditions

$$\frac{\partial E_x}{\partial z}(0,t)=-\mu_0 H_m[\omega\cos(\omega t+\gamma)+\epsilon f_y'(t)], \tag{5}$$

$$\frac{\partial E_y}{\partial z}(0,t)=-\mu_0 H_m[\omega\sin(\omega t+\gamma)+\epsilon f_x'(t)], \tag{6}$$

$$E_x(\infty)=E_y(\infty)=0. \tag{7}$$

Next, we shall look for the periodic solution of the boundary value problem (4)–(7) in the following form:

$$\begin{aligned} E_x(z,t)&=E_x^0(z,t)+\epsilon e_x(z,t),\\ E_y(z,t)&=E_y^0(z,t)+\epsilon e_y(z,t). \end{aligned} \tag{8}$$

By substituting expressions (8) into Eqs. (4) and boundary conditions (8), and equating the terms of like powers of ϵ, we arrive at the following boundary value problems for E_x^0, E_y^0 and e_x, e_y:

$$\frac{\partial^2 E_x^0}{\partial z^2}=\mu_0\frac{\partial J_x(E_x^0,E_y^0)}{\partial t}, \quad \frac{\partial^2 E_y^0}{\partial z^2}=\mu_0\frac{\partial J_y(E_x^0,E_y^0)}{\partial t}, \tag{9}$$

$$\begin{aligned} \frac{\partial E_x^0}{\partial z}(0,t)&=-\omega\mu_0 H_m\cos(\omega t+\gamma),\\ \frac{\partial E^0}{\partial z}(0,t)&=-\omega\mu_0 H_m\sin(\omega t+\gamma), \end{aligned} \tag{10}$$

$$E_x^0(\infty)=E_y^0(\infty)=0, \tag{11}$$

and

$$\frac{\partial^2 e_x}{\partial z^2}=\mu_0\frac{\partial}{\partial t}\left(\frac{\partial J_x}{\partial E_x}(E_x^0,E_y^0)e_x+\frac{\partial J_x}{\partial E_y}(E_x^0,E_y^0)e_y\right), \tag{12}$$

$$\frac{\partial^2 e_y}{\partial z^2}=\mu_0\frac{\partial}{\partial t}\left(\frac{\partial J_y}{\partial E_x}(E_x^0,E_y^0)e_x+\frac{\partial J_y}{\partial y}(E_x^0,E_y^0)e_y\right), \tag{13}$$

 0021-8979/94/76(10)/6956/3/$6.00 © 1994 American Institute of Physics

$$\frac{\partial e_x}{\partial x}(0,t)=-\mu_0 H_m f_y'(t), \quad \frac{\partial e_y}{\partial z}(0,t)=\mu_0 H_m f_x'(t), \tag{14}$$

$$e_x(\infty)=e_y(\infty)=0. \tag{15}$$

The boundary value problem (9)–(11) describes the penetration of a circularly polarized plane wave into the superconducting half-space. The solution of this problem has been found in Ref. 2. For the case when the initial phase, γ, is such that the initial phase of $\mathbf{E}^0$ on the boundary ($z=0$) is equal to zero, this solution is given by the following expressions:

$$E_x^0(z,t)=E_m\left(1-\frac{z}{z_0}\right)^{\alpha'} \cos[\omega t+\theta(z)], \tag{16}$$

$$E_y^0(z,t)=E_m\left(1-\frac{z}{z_0}\right)^{\alpha'} \sin[\omega t+\theta(z)], \tag{17}$$

$$z_0=\frac{\sqrt[4]{2n(n+1)(3n+1)^2}}{\sqrt{\omega\mu_0\sigma_m}(n-1)}, \quad \sigma_m=kE_m^{1/n-1}, \tag{18}$$

$$\theta(z)=\alpha'' \ln(1-z/z_0), \tag{19}$$

$$\alpha'=\frac{2n}{n-1}, \quad \alpha''=\frac{\sqrt{2n(n+1)}}{n-1}, \tag{20}$$

and E_m can be found from the equation

$$H_m=\frac{|\alpha'+i\alpha''|}{\omega\mu_0 z_0}E_m. \tag{21}$$

By substituting (16) and (17) into Eqs. (12) and (13) and by using expressions (2), after simple but somewhat lengthy transformations we arrive at the following equations for e_x and e_y:

$$\frac{\partial^2 e_x(z,t)}{\partial z^2}=\mu_0\sigma_m\left(1-\frac{z}{z_0}\right)^2\frac{\partial}{\partial t}\left[\left(\frac{1+n}{2n}+\frac{1-n}{2n}\cos[2\omega t+2\theta(z)]\right)e_x(z,t)+\frac{1-n}{2n}\sin[2\omega t+2\theta(z)]e_y(z,t)\right], \tag{22}$$

$$\frac{\partial^2 e_y(z,t)}{\partial z^2}=\mu_0\left(1-\frac{z}{z_0}\right)^2\frac{\partial}{\partial t}\left[\frac{1-n}{2n}\sin[2\omega t+2\theta(z)]e_x(z,t)+\left(\frac{1+n}{2n}-\frac{1-n}{2n}\cos[2\omega t+2\theta(z)]\right)e_y(z,t)\right]. \tag{23}$$

Equations (22) and (23) are coupled linear partial differential equations of parabolic type with a variable in time and space coefficients. We would like to find the periodic solutions of these equations, subject to the boundary conditions (14) and (15). To this end, we introduce new complex valued state variables:

$$\varphi(z,t)=e_x(z,t)+ie_y(z,t),$$
$$\psi(z,t)=e_x(z,t)-ie_y(z,t). \tag{24}$$

By using these state variables, and some simple transformations, we can represent Eqs. (22) and (23) in the following form:

$$\frac{\partial^2\varphi}{\partial z^2}=\mu_0\sigma_m\frac{1-n}{2n}\left(1-\frac{z}{z_0}\right)^{-2}\frac{\partial}{\partial t}\left[\frac{1+n}{1-n}\varphi+\left(1-\frac{z}{z_0}\right)^{i2\alpha''}e^{i2\omega t}\psi\right], \tag{25}$$

$$\frac{\partial^2\psi}{\partial z^2}=\mu_0\sigma_m\frac{1-n}{2n}\left(1-\frac{z}{z_0}\right)^{-2}\frac{\partial}{\partial t}\left[\frac{1+n}{1-n}\psi+\left(1-\frac{z}{z_0}\right)^{-i2\alpha''}e^{-i2\omega t}\varphi\right]. \tag{26}$$

Assuming that functions $f_x(t)$ and $f_y(t)$ in boundary conditions (14) are function of half-wave symmetry (the case that is usually of the most practical interest), we conclude that $e_x(z,t)$ and $e_y(z,t)$ will also be the functions of half-wave symmetry. For this reason, we will use the following Fourier series for $\varphi(z,t)$ and $\psi(z,t)$:

$$\varphi(z,t)=\sum_{k=-\infty}^{\infty}\varphi_{2k+1}(z)e^{i(2k+1)\omega t}, \tag{27}$$

$$\psi(z,t)=\sum_{k=-\infty}^{\infty}\psi_{2k+1}(z)e^{i(2k+1)\omega t}. \tag{28}$$

It is clear from (24), (27), and (28) that

$$\varphi_{2k+1}^*(z)=\psi_{-2k-1}(z), \quad \psi_{2k+1}^*(z)=\varphi_{-2k-1}(z), \tag{29}$$

where the superscript "*" means a complex conjugate quantity.

By substituting (27) and (28) into (25) and (26), and by equating the terms with the same exponents, after simple transformations we derive

$$\left(1-\frac{z}{z_0}\right)^2\frac{d^2\varphi_{2k+1}}{dz^2}=i\chi_{2k+1}\left[a\varphi_{2k+1}-\left(1-\frac{z}{z_0}\right)^{i2\alpha''}\psi_{2k-1}\right], \tag{30}$$

$$\left(1-\frac{z}{z_0}\right)^2\frac{d^2\psi_{2k-1}}{dz^2}=i\chi_{2k-1}\left[a\psi_{2k-1}+\left(1-\frac{z}{z_0}\right)^{-i2\alpha''}\varphi_{2k+1}\right] \quad (k=0,\pm1,\pm2,\ldots), \tag{31}$$

where we have introduced the following notations:

$$a=\frac{1+n}{1-n}, \quad \chi_{2k+1}=(2k+1)\omega\mu_0\sigma_m\frac{1-n}{2n}. \tag{32}$$

Thus, we have reduced the problem of integration of partial differential equations (25)–(26) to the solution of infinite set of ordinary differential equations with respect to Fourier coefficients φ_{2k+1} and ψ_{2k-1}. The remarkable property of these simultaneous equations is that they are only coupled by pairs. It allows one to solve each pair of these coupled equations separately. After φ_{2k+1} and ψ_{2k-1} are found, we can compute $\varphi(z,t)$ and $\psi(z,t)$, and then $e_x(z,t)$ and $e_y(z,t)$. Another simplification is that according to (29) it suffices to solve coupled equations (30) and (31) only for non-negative values of k.

We shall seek a solution of the coupled equations (30) and (31) in the form

$$\varphi_{2k+1}(z)=A_{2k+1}\left(1-\frac{z}{z_0}\right)^{\beta},$$
$$\psi_{2k-1}=B_{2k-1}\left(1-\frac{z}{z_0}\right)^{\beta-i2\alpha''}. \tag{33}$$

By substituting (33) into (30) and (31), we end up with the following simultaneous homogeneous equations with respect to A_{2k+1} and B_{2k-1}:

$$(\beta^2-\beta-i\chi_{2k+1}z_0^2a)A_{2k+1}-i\chi_{2k+1}z_0^2B_{2k-1}=0, \tag{34}$$

$$-i\chi_{2k-1}z_0^2A_{2k+1}+[(\beta-i2\alpha'')^2-(\beta-i2\alpha'')-i\chi_{2k-1}z_0^2a]B_{2k-1}=0. \tag{35}$$

The above homogeneous equations have a nonzero solution for A_{2k+1} and B_{2k-1} if and only if the corresponding determinant is equal to zero. This yields the following characteristic equation for β:

$$(\beta^2-\beta-i\chi_{2k+1}z_0^2a)[(\beta-i2\alpha'')^2-(\beta-i2\alpha'')-i\chi_{2k-1}z_0^2a]+\chi_{2k+1}\chi_{2k-1}z_0^4=0. \tag{36}$$

From expressions (32) and (18), we find

$$\chi_{2k+1}z_0^2a=\frac{(2k+1)(3n+1)(n+1)}{(n-1)^2}\sqrt{\frac{n+1}{2n}}, \tag{37}$$

$$\chi_{2k+1}\chi_{2k-1}z_0^4=\frac{(4k^2-1)(3n+1)(n+1)}{(n-1)^2}\sqrt{\frac{n+1}{2n}}. \tag{38}$$

From the last two expressions, we conclude that the coefficients of the characteristic equation (36) depend on the exponent, n, of the power law and k. Consequently, the roots of this equation also depend only on n and k. It can be proven that the above characteristic equation has two roots $\beta_1(n,k)$ and $\beta_2(n,k)$ with positive real parts. After these roots are found, the solution of coupled equations (30) and (31) can be represented in the form

$$\varphi_{2k+1}(z)=A_{2k+1}^{(1)}\left(1-\frac{z}{z_0}\right)^{\beta_1}+A_{2k+1}^{(2)}\left(1-\frac{z}{z_0}\right)^{\beta_2}, \tag{39}$$

$$\psi_{2k-1}(z)=B_{2k-1}^{(1)}\left(1-\frac{z}{z_0}\right)^{\beta_1-i2\alpha''}+B_{2k-1}^{(2)}\left(1-\frac{z}{z_0}\right)^{\beta_2-i2\alpha''}, \tag{40}$$

where, for the sake of notational simplicity, we have omitted the dependence of β_1 and β_2 on n and k.

From boundary conditions (14) and expressions (24) and (34), we obtain the following equations for $A_{2k+1}^{(1)}$, $A_{2k+1}^{(2)}$, $B_{2k-1}^{(1)}$, and $B_{2k-1}^{(2)}$:

$$\beta_1z_0A_{2k+1}^{(1)}+\beta_2z_0A_{2k+1}^{(2)}=\mu_0H_m(-f'_{y,2k+1}+if'_{x,2k+1}), \tag{41}$$

$$(\beta_1-i2\alpha'')z_0B_{2k-1}^{(1)}+(\beta_2-i2\alpha'')z_0B_{2k-1}^{(2)}=\mu_0H_m(-f'_{y,2k-1}-if'_{x,2k-1}), \tag{42}$$

$$(\beta_1^2-\beta_1-i\chi_{2k+1}z_0^2a)A_{2k+1}^{(1)}-i\chi_{2k+1}z_0^2B_{2k-1}^{(1)}=0, \tag{43}$$

$$(\beta_2^2-\beta_2-i\chi_{2k+1}z_0^2a)A_{2k+1}^{(2)}-i\chi_{2k+1}z_0^2B_{2k-1}^{(2)}=0, \tag{44}$$

where $f'_{x,2k+1}$ and $f'_{y,2k+1}$ are complex Fourier coefficients of f'_x and f'_y.

By solving simultaneous equations (41)–(44), we can find coefficients $A_{2k-1}^{(1)}$, $A_{2k+1}^{(2)}$, $B_{2k-1}^{(1)}$, and $B_{2k-1}^{(2)}$. Then, by using (39), (40), (27)–(28), and (24), we can determine perturbations $e_x(z,t)$ and $e_y(z,t)$, which, in turn, can be used in (8) to compute the total electric field.

In conclusion, consider the particular case when

$$f_x(t)=\cos\omega t, \quad f_y=\sin\omega t. \tag{45}$$

This case corresponds to elliptical polarization of the incident field. It is easy to see that in this case, the right-hand sides of Eqs. (41) and (42) are equal to zero for all k except $k=1$. This means that only first and third harmonics are not equal to zero. We have reached this conclusion, because we have considered only first-order perturbations with respect to ϵ. If we consider higher-order perturbations with respect to ϵ, we shall recover higher-order harmonies of the electric field.

From the purely mathematical point of view, it is remarkable that the solution of coupled equations (22)–(23), corresponding to the boundary conditions (14), (15) and (45), contains only the first and third harmonics. Probably, this is because the coupled PDE's (22) and (23) have inherited some symmetry properties from the unperturbed problem, corresponding to the circular polarization of the incident wave.

Finally, we note that in the limiting case of $n\to\infty$, we obtain from the presented formulas the distribution of electromagnetic fields for ideal (sharp) resistive transition.

Proximity effect in MBE-grown superconducting/spin-glass multilayers

Carlos W. Wilks, Brad N. Engel, and Charles M. Falco
Department of Physics and the Optical Sciences Center, University of Arizona, Tucson, Arizona 85721

We have grown epitaxial superconductor/spin-glass multilayers, Nb/CuMn, as well as complimentary nonmagnetic Nb/Cu multilayers by molecular beam epitaxy. To probe the interaction of superconductivity and magnetism, we measured the resistivity and ac susceptibility as a function of temperature for multilayers of nominally constant Nb thickness and varying normal-metal thickness. The reduction of the transition temperature of the Nb/Cu multilayers with increasing Cu thickness is in excellent agreement with the de Gennes–Werthamer proximity effect theory. The inclusion of Mn in the Cu causes a significant additional suppression of the transition temperatures relative to the Nb/Cu multilayers. The extension of the de Gennes–Werthamer theory to include the effects of random magnetic impurities agrees well with the data from the Nb/CuMn multilayers for small CuMn layer thicknesses. However, deviations occur at the largest CuMn thicknesses studied. These deviations between the data and theory may be due to a decoupling of the Nb layers, as a result of the spin-glass ordering, causing a three-dimensional to two-dimensional crossover.

I. INTRODUCTION

The coexistence of superconductivity and magnetism has been the focus of many studies over the years, because magnetism is, in general, detrimental to the superconducting state. Nonetheless, ferromagnetism and antiferromagnetism have been shown to coexist with superconductivity.[1,2] Superconductivity can also coexist with spin-glass materials in which the localized impurity spins interact through the conduction electrons. Below the spin-glass freezing temperature, the spins can be considered frozen in the random direction of the local magnetic field instead of forming any long-range magnetic order.

While most of the work to date on the interaction of magnetism and superconductivity has been on bulk alloys with magnetic impurity substitutions, there has been some more recent work on artificial structures, namely, multilayers.[3] To date, the majority of the superconducting/magnetic multilayers have been fabricated in high vacuum systems (10^{-7}–10^{-8} Torr) using sputtering, electron beam, and/or thermal evaporation. Our work utilizes molecular beam epitaxy (MBE) techniques (10^{-10}–10^{-12} Torr) in order to fabricate high-quality multilayers with improved properties.

We chose to study the interaction of magnetism and superconductivity in the Nb/CuMn multilayer system, where CuMn is a well-studied spin-glass system. Due to finite size effects,[4] the spin-glass freezing temperature, T_f, where the magnetic moments locally align, scales with the thickness of the CuMn film. The Nb transition temperature also depends on film thickness, decreasing from the bulk value as the film thickness is reduced. These two effects allow us to tailor the multilayer system, such that either T_c or T_f is higher. This allows the interplay of the two phenomena to be studied. Work on sputtered Nb/CuMn multilayers has been recently reported.[5,6] We have also deposited the complementary Nb/Cu multilayer system as a nonmagnetic baseline reference for comparison.

II. EXPERIMENTAL PROCEDURES

The multilayers were grown in a Perkin-Elmer 433-S MBE system with a base pressure of $\sim 5\times10^{-11}$ Torr. *In situ* reflection high-energy electron diffraction (RHEED) and low-energy electron diffraction (LEED) were used for structural characterization. The Nb and Cu are deposited using separate electron beam guns, while the Mn is deposited from an effusion cell. The multilayers are grown on Si(111) wafers. The wafers are first dipped in a 2% HF acid solution and then immediately annealed to 850 °C in the MBE system. RHEED is performed on the substrate to check the quality of the resultant 7×7 Si(111) reconstruction. The reconstruction is a good indication of a high-quality impurity free surface. We then grow a 40 Å epitaxial fcc Cu(111) buffer layer on the Si wafer once it has cooled to room temperature. The buffer layer is a necessary seed to grow bcc Nb(110). Using this technique, the Nb and the Cu layers grow epitaxially with their densest packed planes parallel to the substrate. RHEED is again employed during the growth of the buffer layer to monitor crystal quality.

During all depositions, the substrate is rotated at 10 rpm about its normal to enhance the uniformity of the films. The pressure in the MBE system during the multilayer deposition is in the $2\text{–}5\times10^{-9}$ Torr range. The Nb is deposited first at a rate of 0.6 Å/s followed by a Cu deposition at a rate of 0.3 Å/s. For Nb/CuMn, the CuMn layers are formed by a codeposition of Cu at a rate of 0.3 Å/s and Mn at 0.021 Å/s, resulting in a spin-glass having seven at. % Mn. Again, we use RHEED to probe the top surface of the multilayer to confirm epitaxial growth. All the multilayers consist of ten bilayers, in which the thickness of the Nb layers was constant at nominally 230 Å and the normal-metal thickness was varied. The actual layer thicknesses of each of the multilayers was determined from the Rutherford backscattering spectroscopy (RBS). In Table I, we present the measured layer thicknesses, the expected spin-glass freezing temperatures and the measured multilayer transition temperatures for this series of multilayers.

	257	24		8.93
	247	61		8.49

Low temperature measurements were performed using a charcoal-pumped ^{3}He cryostat. Both the resistance and the ac susceptibility measurements were simultaneously measured using ac lock-in techniques. A calibrated Ge thermometer in close thermal contact to the samples was used to measure the temperature. The superconducting transition temperatures of the multilayers are determined upon cooling from the onset of the susceptibility transition.

III. RESULTS AND DISCUSSION

High and low angle x-ray diffraction are performed on each multilayer. From the high angle x-ray diffraction scans, we find the Nb grows in the (110) orientation, and the Cu or CuMn grows in the (111) orientation, as expected. We present, in Fig. 1(a), the high angle x-ray scan, and in Fig. 1(b), the low angle x-ray scan for a Nb(239 Å)/CuMn(53 Å) multilayer. The high angle scan is representative for all the multilayers made. From the peak positions in the high angle scans, we find the Nb lattice constant is compressed by less than 2% relative to bulk Nb, while the Cu lattice constant is expanded by less than 1% relative to bulk Cu. Low angle x-ray diffraction was also performed as a check on the multilayer quality and to obtain an additional measure of the bilayer thickness. This value was then compared to the results obtained from RBS. Multilayer Bragg peaks are seen in the low angle scans for multilayers with a Cu or CuMn thickness of 9 Å or greater. Fitting of the low angle x-ray scans to a Fresnel-type optical model yields values for the interfacial roughness of less than 8 Å. This agrees well with the maximum top layer roughness, as determined by atomic force microscopy.

The relevant theory to describe the superconducting properties of our Nb/Cu multilayers is the de Gennes–Werthamer[7] theory. It applies to the case when the materials in the superconducting/normal-metal sandwich are in the dirty limit. This theory requires the coherence length, ξ_i, of each material be smaller than the layer thickness, d_i, and the mean-free paths, l_i, of each material be smaller than the coherence length. The extension of this theory to include magnetic impurities in the normal metal was done by Hauser, Theuerer, and Werthamer.[8] The equations that relate the physical parameters of the individual materials to the transition temperature, T_c, of the multilayer are given in the paper by Banerjee.[9]

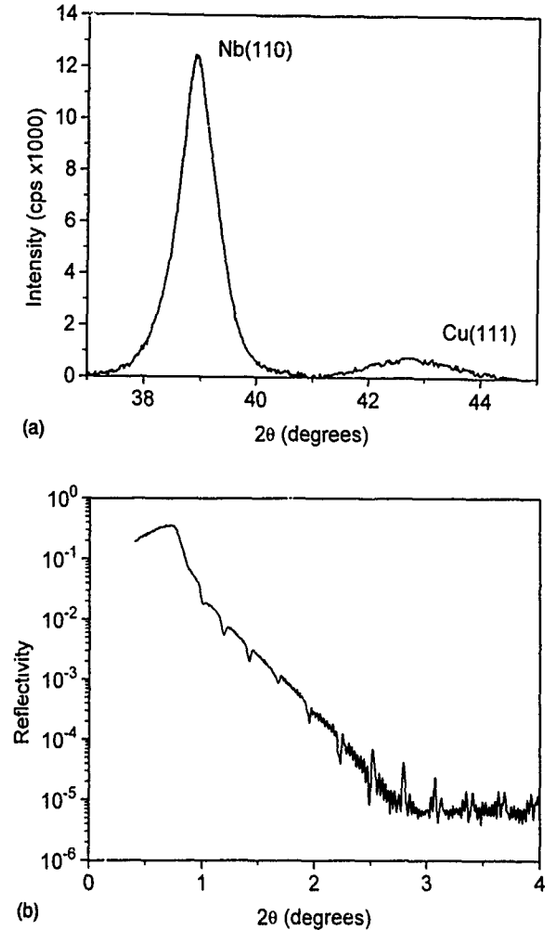

FIG. 1. (a) High angle and (b) low angle x-ray scans of the Nb(239 Å)/CuMn(53 Å) multilayer.

As a verification of our Nb film quality, a thick Nb film was grown and T_c determined. For an 860 Å Nb film grown on a 40 Å Cu buffer layer, $T_c = 9.27$ K, in good agreement with the transition temperature of bulk Nb. Thus, we can rule out the possibility of localization effects[10] and lifetime broadening of the density of states[11] as a cause of the reduction in T_c in our multilayers.

In Fig. 2, we show the transition temperature of our multilayer series as a function of normal-metal thickness. The upper data set (squares) is for the Nb/Cu multilayers, while the middle set (diamonds) is for the Nb/CuMn series. Applying the de Gennes–Werthamer theory to the Nb/Cu multilayers yields excellent agreement between the measured and calculated values for T_c with no adjustable parameters. The calculated values are within 0.02 K of the measured T_c values for all three of the Nb/Cu multilayers. The inclusion of Mn in the Cu layers causes a dramatic decrease of the transition temperature of the Nb/CuMn multilayers, as expected for these magnetic atoms.

When a dilute concentration of randomly oriented and distributed magnetic moments are included in the normal-metal, the equation relating T_c to the relevant physical parameters is modified by the inclusion of an electron relaxation time due to the magnetic pair breaking. Strictly speak-

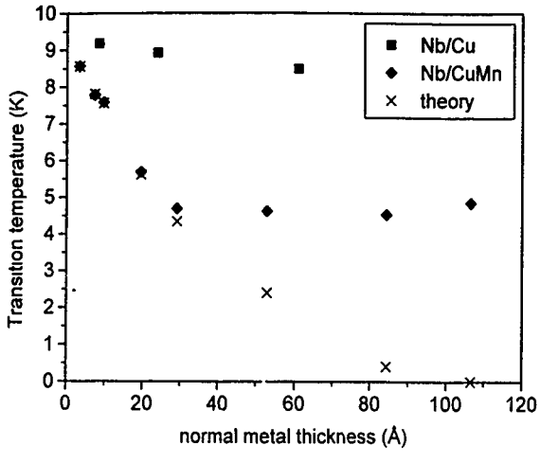

FIG. 2. Transition temperatures of the multilayers as a function of normal-metal thickness.

ing, the extension of the de Gennes–Werthamer theory to include random magnetic impurities should not apply to our multilayers with thick CuMn layers, where the Mn moments locally order. Applying the theory to the multilayer with a CuMn layer thickness of 3.3 Å, where $T_f < T_c$, and where the theory is most likely to be valid, yields a reasonable value for the electron relaxation time, τ_s, of 9.6×10^{-15} s. Using this value of τ_s as an input for the theory, we can calculate T_c values for the other multilayers. This yields the cross points marked theory in Fig. 2. The theory is in good agreement for the first four data points (the theory is set equal to the first data point), but then falls well below the measured values at larger thicknesses. Clearly the magnetic extension of the Werthamer theory fails to describe all the data.

For those multilayers with $T_f > T_c$, where the Mn moments are in a locally more ordered state, one would expect a greater suppression of T_c than predicted by the random magnetic impurity model. This is not the case. It is interesting to note that the deviation between the data and the theory begins near the CuMn thickness, where T_f becomes larger than T_c. In addition, as the CuMn layer thickness is increased, a three-dimensional to two-dimensional crossover decoupling the Nb layers is expected. Further work is needed to determine if the deviations from the theory are a result of a dimensional crossover or are driven by the spin-glass ordering of the CuMn. Parallel critical field measurements are now underway to investigate at what normal-metal thickness the three-dimensional to two-dimensional crossover takes place.

IV. CONCLUSION

We have grown epitaxial spin-glass/superconductor multilayers of Nb and CuMn, as well as the nonmagnetic Nb/Cu multilayers using MBE. The suppression of T_c for the Nb/Cu multilayers is in excellent agreement with the de Gennes–Werthamer proximity effect theory, without the complication of localization or lifetime broadening of the density of states. At small CuMn thicknesses, the additional depression of T_c caused by the inclusion of Mn in the Cu can be described by the extension of the de Gennes–Werthamer theory for random magnetic impurities. The data and theory disagree for the larger CuMn layer thicknesses. This may be due to a three-dimensional to two-dimensional crossover decoupling the Nb layers, and is currently under investigation.

The purpose of this work was to utilize the nonlinear current-voltage properties of induced grain boundaries in high temperature superconducting $YBa_2Cu_3O_{7-x}$ thin films to fabricate a planar microwave mixer. The experiment involved constructing a coplanar waveguide microwave circuit, the center conductor of which had a constriction patterned in it containing a single high angle grain boundary, thus forming a weak link junction. Analysis was provided by use of the resistively shunted junction model with excess current.

I. INTRODUCTION

Sufficient precedent exists, as a result of previous work in years past on low temperature superconducting mixers, which provides the motivation for conducting extensive research in microwave and millimeter wave mixers using high temperature superconductors. For example, theoretical calculations on lower bounds on noise temperature have been determined for superconducting-insulator-superconducting (SIS) mixers employing quasiparticle tunneling.[1] These theoretical limits have been approached experimentally, providing noise temperatures below those currently available in semiconductor devices.[2] At least one experimental result has demonstrated a positive conversion gain using low temperature superconducting tunnel junctions.[3]

Since the introduction of high temperature superconductors, several reports of mixing have appeared. Some of these measurements were performed using the transition resistance occurring above the temperature at which the dc resistance falls to zero.[4] Other successful experiments in mixing have been reported using materials other than $YBa_2Cu_3O_{7-x}$ (YBCO).[5] Microwave mixing using YBCO and employing weak link effects, have been reported. These devices contain weak links involving polycrystalline materials with multiple randomly oriented grain boundaries or involving step edge junctions.[6–9] Some of these devices, indeed, have shown remarkable results in terms of conversion loss in mixing at microwave frequencies.[10]

The purpose here has been to construct truly planar superconducting YBCO mixers employing artificially induced grain boundaries with predictable angles, and to characterize these grain boundary mixers by employing suitable physical models.

II. EXPERIMENTAL DETAILS

The starting material was an epitaxial YBCO thin film, which was grown by laser ablation deposition on a bicrystalline $SrTiO_3$ substrate.[11] This substrate was composed of two crystals joined together with an interface that formed a 36.8° angle.

The coplanar waveguide circuit was patterned on this thin film, such that a 30 μm wide microbridge was formed, which spanned the bicrystal boundary, and thereby induced a single grain boundary in the microbridge, as is evident in the mixer circuit depicted schematically in Fig. 1. The pattern was obtained by conventional wet etching.

This procedure resulted in circuits with constrictions that would contain a single grain boundary with an angle of 36.8°. Such circuits exhibit greatly reduced critical current densities and weak link properties.[12,13]

The etched circuit was mounted on an acrylic block, and the coplanar waveguide was connected to 50 Ω cables by means of SMA to microstrip launchers. The dc probes for applying bias current and measuring the voltage were composed of stainless steel spring loaded contacts, which mated with the surface of the center conductor in the circuit. This configuration is also shown in Fig. 1.

Output from the two microwave sources used for mixing could be independently adjusted in power and frequency. The signals were combined in a directional coupler, and then passed through a dc block and into the device. The output signal passed through the output launcher from the device and through a second dc block into a high gain spectrum

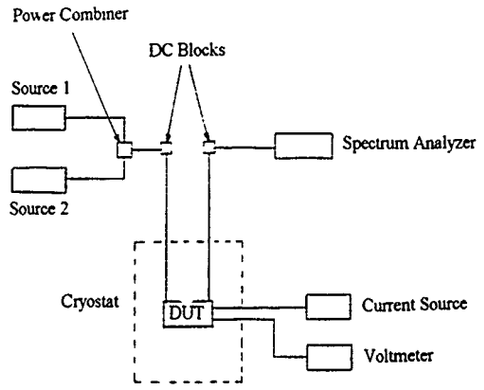

FIG. 2. Schematic diagram of the experimental microwave mixer test apparatus.

analyzer. The experimental apparatus is depicted in Fig. 2.

First, current versus voltage characteristic curves were obtained for the junction, in the absence of microwave energy, and recorded. When the junction was driven by the local oscillator, with microwave energy, current steps were produced in the current voltage characteristic curve. These steps appeared at voltages that were integral multiples of the flux quantum times the frequency. Both characteristic curves are overlaid in Fig. 3. The current steps, evident in Fig. 3, were the basis for adjustments of the current bias levels, and were the nonlinear contribution of the circuit, which was utilized for down-conversion mixing.

III. THEORETICAL MODELING

Modeling of the coplanar waveguide circuit involved the use of some approximations of the standard equations.[14] Approximate values for the transmission line characteristic impedances were obtained using the value of $\epsilon_r=9190$, obtained from published data[15] and a value of tan $\delta=0.03$ obtained from literature.[16] From the characteristic impedances, together with the transmission line dimensions, and by using transmission line matrix methods, it was possible to calculate the input impedance of the transmission line at the signal frequency and the local oscillator frequency. The value obtained was found to be $Z_{IN,S}=1.368-j0.116$ and $Z_{IN,LO}=1.396+j0.144$. Using the input impedances and the transmission line matrices, together with the knowledge of the input signal power and input local oscillator power, it was possible to estimate the respective currents on the microbridge portion of the transmission line. This was found to be $I_S=-555.8\times10^{-6}-j562.4\times10^{-6}$ A and $I_{LO}=483.8\times10^{-6}+j187.5\times10^{-6}$ A.

With an estimated value of the currents due to the two input microwave signals, and a knowledge of the bias current, a calculation for the output current level was obtained using the following two equations:

$$I=I_c \sin \phi \tag{1}$$

and

$$-\frac{\hbar}{q}\frac{d\phi}{dt}=R_N(I_B+I_{LO}\cos \omega_{LO}t+I_S \cos \omega_S t-I_0 - I_c \sin \phi). \tag{2}$$

Equations (1) and (2) are recognized as the Josephson relations used in the resistively shunted junction model for the shunted Josephson junction, with excess current, I_0,[17] I_B is the dc bias current, I_0 is the superconducting excess shunt current, R_N is the normal mode resistance obtained from the characteristic curves, and q is the superconducting pair charge. These equations were solved numerically using the technique of Runge–Kutta in double precision and then subject to a discrete Fourier transform to extract the harmonic content. These calculations yielded the result for the magnitude of $I_{i.f.}$, the current of the intermediate frequency at the junction, which was $I_{i.f.}=4.25\times10^{-6}$ A$=3.00\times10^{-6}$ A (rms). The calculated value of $I_{i.f.}$ was then used again in the matrix representation of the transmission line using impedances determined at the intermediate frequency. The result was an output power of -82 dB m.

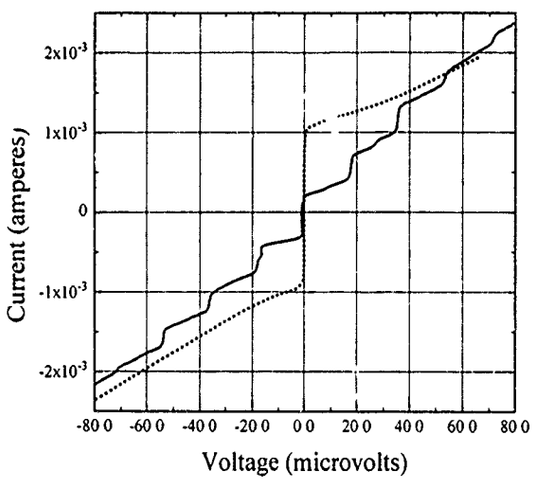

FIG. 3. Current voltage characteristic curves for YBCO grain boundary weak link junction. Dotted line is without rf signal. Solid line with rf energy at 8.7 GHz.

IV. RESULTS AND DISCUSSION

When the circuit was dc current biased near any one of the current steps, and when both the microwave local oscillator and the microwave signal were applied, an intermediate frequency was observed at the difference frequency. In the experiments, the local oscillator was at 8.7 GHz and the signal frequency was at 7.7 GHz, therefore the difference frequency was measured at 1.0 GHz. The input signals are shown as an inset in Fig. 4 and output intermediate frequency is shown in Fig. 4.

It was determined that the conversion loss of the mixer was dependent upon the input power and the bias current. Approximate relative values of conversion gain are shown in Fig. 5. It was evident during the experiment that mixing was absent for bias values between steps, whereas the i.f. signal was maximum when the bias current was located within the

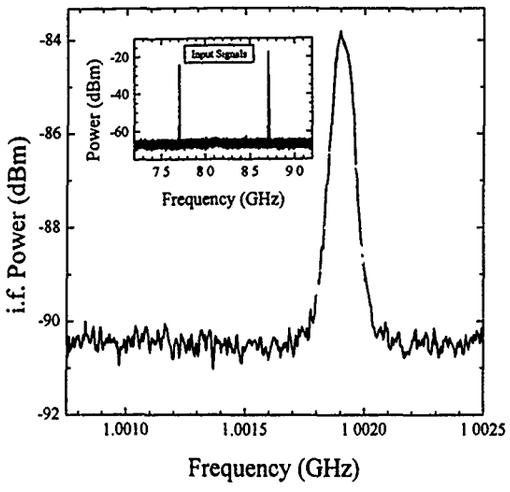

FIG. 4. Output intermediate frequency, i.f., signals at temperature 45 K, with dc current bias of 0.78 mA. Input microwave signals are shown in the inset.

range of values of the current steps. The smallest conversion loss appeared at current values corresponding to the $n = \pm 1$ steps.

The bias current levels were theoretically and experimentally observed to provide mixing when biased at the steps. The measured conversion loss agrees with the theoretical calculation to within 3 dB.

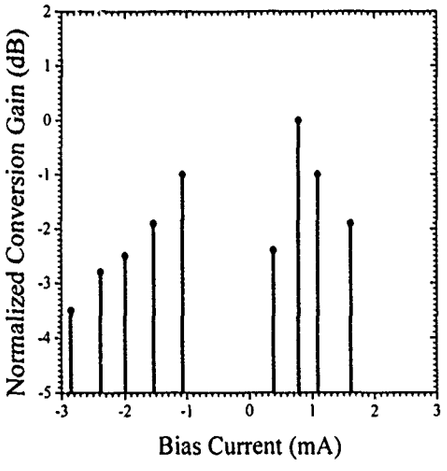

FIG. 5. Approximate experimental values of conversion gain for YBCO grain boundary mixer at $T = 45$ K vs bias current. Values are relative to the minimum conversion loss at 0.78 mA bias current.

V. CONCLUSION

The coplanar waveguide geometry allowed the fabrication of a high frequency transmission line in one plane. This eliminated the need for copper grounding blocks, and allowed the circuit to be fabricated using standard wet etch technology. Thus, there is potential use in monolithic microwave integrated circuits.

The use of engineered grain boundary junctions provided the opportunity to characterize the intrinsic operation of the weak link junctions used as mixers. It allowed the reproducible fabrication and testing of weak link junctions with similar results, since the grain boundary angles could be assured during their construction. However, by using $SrTiO_3$ substrates, the resulting embedding impedances limited the amount of i.f. power efficiently coupled to the output.

Using the resistively shunted junction model with excess current, it was possible to mathematically model the operation of superconducting grain boundary mixers using the coplanar waveguide configuration. The calculations are in excellent agreement with the measured results, and should provide insight in further developments.

Superconducting $YBa_2Cu_3O_{7-x}/Y_4Ba_3O_9$ multilayers: Field independent critical current and dimensional crossover (abstract)

Jun-Hao Xu, A. M. Grishin, and K. V. Rao
Department of Condensed Matter Physics, Royal Institute of Technology, S-100 44 Stockholm, Sweden

A new class of c-axis-oriented $YBa_2Cu_3O_{7-x}/Y_4Ba_3O_9$ (YBCO/YBO) multilayer films with YBCO and YBO individual thicknesses ranging from 24 to 156 Å have been fabricated by a single target on-axis biased rf magnetron sputtering technique on $LaAlO_3$ (001) substrates. SQUID dc magnetic measurements reveal a striking feature of magnetic field independent critical current $j_c(T)$ from 5 K to almost near superconducting transition T_c. For thin YBCO layer thickness the magnitude of j_c is found to decrease as $(1-T/T_c)^2$, and exponentially with the thickness of the isolating spacer YBO. It is distinctly shown that $j_c(T)$ in the (**a**,**b**) plane is determined by interlayer Josephson current. All the SQUID data for the temperature dependencies of magnetization for a few families of multilayers with thin YBCO layers are shown to scale and collapse into a single universal behavior consistent with a model of "slipped out pancake vortices in Josephson coupled heterostructures." On approaching T_c, the characteristics of critical current j_c change gradually from the field independent behavior to another dependence similar to an ordinary $H^{-1/2}$ dependence typical for collective pinning of the vortex lattice in the YBCO single layer film. This suggests that a dimensional crossover takes place when the quantum coherence between individual YBCO layers sets. The crossover temperature is found to depend on the multilayer period and individual thicknesses of superconducting and isolating layers while a linear temperature dependence of j_c appears for multilayers with thick YBCO layers.

Schematic frictional model for interacting vortices in an isotropic superconducting plate (abstract)

J. S. Kouvel[a] and S. J. Park
Department of Physics, University of Illinois, Chicago, Illinois 60680

In the simple model proposed, repulsive intervortex forces are balanced by containing forces produced by the external field (H) and by frictional forces representing the effects of pinning on displaced vortices. For the field-cooled (FC) state, whose vortex density is presumably uniform, the empirical fact that the average flux density ($\bar{B}$) in nearly equal to H yields an operational inverse-square dependence of the intervortex force on the intervortex spacing. For both the FC and zero-field-cooled (ZFC) states, expressions are derived for $\bar{B}$ vs H (including the remanences at $H=0$) and for the profiles of B across the sample thickness. Calculations of these properties are compared with experiment and with the macroscopically related critical-state model, revealing again that the pinning forces are strongly dependent on H. The frictional interacting-vortex model is also used in deriving the critical current as a transport property of the FC and ZFC states.

Spin-polarized photoemission from quantum well and interface states (invited)

C. Carbone, E. Vescovo, R. Kläsges, and W. Eberhardt
IFF/KFA Jülich, D-52425 Jülich, Germany

O. Rader and W. Gudat
BESSY, D-14195 Berlin, Germany

We examine the role of quantum well and interface states in mediating the coupling between magnetic films. We have studied with spin- and angle-resolved photoemission the electronic structure of Cu on Co(100) and Ag on Fe(100). Noble metal states of *sp*-derived character are found to be spin-polarized upon contact with the magnetic materials. In Cu films up to 10 monolayer thickness polarized states have been observed. These observations are well described within the framework of one-dimensional quantum-well states, for film thicknesses above a few monolayers. In the low coverage regime, the hybridization with the magnetic states of the substrate strongly influences the character and the dispersion of the conduction bands.

I. INTRODUCTION

The origin of the indirect exchange coupling[1] between magnetic layers separated by a nonmagnetic spacer is related to the Fermi surface of the spacer material, in a Ruderman–Kittel–Kasuya–Yasida (RKKY) picture[2] as well as in a quantum well picture.[3] The oscillatory and long range character of the indirect exchange coupling in magnetic multilayers can be explained within the framework of RKKY interactions. Studies based on the RKKY coupling scheme identify the experimentally found oscillations as a Fermi surface effect within the nonmagnetic spacer material.

A full understanding of the coupling mechanisms should require however a detailed description of the conduction band states, explicitly including the modification due to the reduced dimensionality and to the exchange interaction. In interface systems with one magnetic component, the bonding at the interface often induces a polarization in the nonmagnetic material through a spin-dependent electronic hybridization.[4,5] The resulting moment in transition metal overlayers on magnetic substrates depends primarily on the extent of the *d*-*d* hybridization. For a noble metal on a 3*d* ferromagnet the calculated interface moment is very small ($<0.1\ \mu_B$)[4] because of the small degree of overlap between the *d* states of the two metals.

The induced magnetization of the *d* electrons of a nonmagnetic material typically becomes negligible a few atomic layers away from the interface.[4,5] On the other hand, the spin-polarization induced on the more delocalized *sp* states can extend over several layers. Therefore, those states provide a way of mediating the long range indirect coupling among magnetic layers through a wide class of nonmagnetic materials, including transition and noble metals. The recent quantum well approach relates the coupling to *sp*-derived electronic states observable in electron spectroscopies.[6–8] Ortega *et al.*[6] found that the *sp*-derived electronic states of ultrathin noble metal films present some characteristic features of one-dimensional quantum-well states. In addition, their wave vector can be related within a simple picture to the wave vectors of the RKKY coupling in the asymptotic high coverage limit. This unusual set of properties suggested that polarized quantum-well states could provide the coupling through nonmagnetic layers.

Here we review some of our recent experimental results on quantum-well and interface states of noble metal films on magnetic substrates. We applied spin- and angle-resolved photoemission spectroscopy, being directly sensitive to magnetic information, to systems which have shown oscillatory coupling and which can be grown epitaxially on (100) single crystal surfaces. Results from spin-resolved photoemission are presented to clarify some aspects of the oscillatory magnetic coupling through the noble metals, Cu and Ag. The experiments comprise (i) the asymptotic limit of the coupling, where the bulk electronic structure of the nonmagnetic material has developed, and (ii) the low coverage limit, where the hybridization with the magnetic interface is the determining factor.

II. EXPERIMENT

The spin- and angle-resolved photoemission apparatus[9] consists of a spherical energy analyzer coupled to a 100 keV Mott detector for spin analysis. The spectra were measured with monochromatic synchrotron radiation from the storage ring BESSY in Berlin. The experimental geometry allows for a component of the electric field vector perpendicular to the surface plane. Photoemission spectra were measured with photon energies between 10 and 80 eV on the TGM5 and the TGM1 beamlines.

The growth of Cu on Co(100) and Ag on Fe(100) has been characterized by several methods.[10] A full account of our preparation and characterization procedures can be found

 0021-8979/94/76(10)/6966/6/$6.00 © 1994 American Institute of Physics

in our recent and forthcoming publications.[7,11] The measurements presented here were performed on Cu/Co/Cu(100) and Ag/Fe/Ag(100) three-layered systems. The single-crystal substrates were prepared by sputtering and annealing cycles. Epitaxial films were deposited *in situ* by e-beam evaporation. A 20 monolayer thick fcc Co film was grown on Cu at 100 °C. Ultrathin Cu layers were subsequently deposited on Co at room temperature. Similarly, we grew a 10 monolayer thick Fe films on Ag(100), by evaporation on the substrate at room temperature. We produced an overlayer of Ag on Fe by annealing the sample at 250 °C for 30 min. Temperature and time of the annealing were chosen in order to achieve a complete monolayer coverage, as indicated by the saturation of the Ag $4d$/Fe $3d$ intensity ratio in the photoemission spectra. The system prepared in this way, consisting of a Ag(1 ML)/Fe(10 ML)/Ag(100), is stable upon further heating and upon cooling to room temperature. The binding energy of Ag-related spectral features corresponds to those obtained by Brookes *et al.*[12] for an evaporated Ag monolayer on Fe(100).

We observe a sharp low-energy electron diffraction (LEED) pattern with low background at all stages of the epitaxial growth. The distinct and intense "quantum-well states" observed in the photoemission spectra, shown in Sec. III, also demonstrate the good quality of the overlayer structure. According to Ortega *et al.*[6] these states provide a very strict test for the smoothness and crystalline order of the overlayer. The Co and Fe substrates have been magnetized along the in-plane ⟨011⟩ and ⟨001⟩ directions, respectively, which are the easy axes of these ferromagnetic thin films. Photoemission spectra have been measured in magnetic remanence. The sample magnetization was aligned parallel to the spin-sensitive direction of the spin detector.

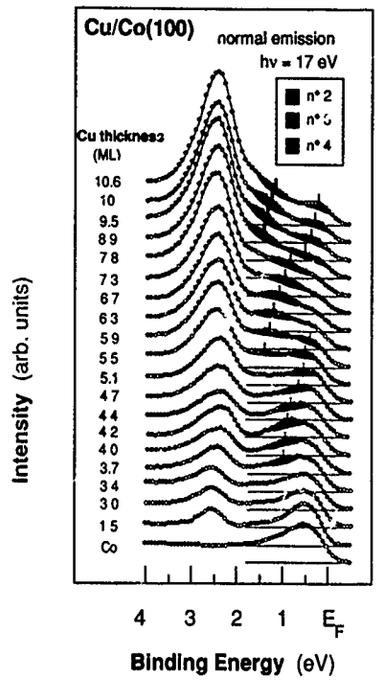

FIG. 1. Angle-resolved photoemission spectra of Cu films on Co(100). The spectra are measured for normal emission with 17 eV photon energy. The emission from Cu sp-derived states is shown by the gray-shadowed areas. These states are labeled according to the definitions in Ref. 6.

III. RESULTS AND DISCUSSION

A. Cu on Co(100): Spin-polarized quantum-well states

For Cu on Co(100) we have explored the sp-derived quantum-well states up to large thicknesses, where the electronic structure of the spacer layer is believed to be largely independent of that of the ferromagnetic substrate (asymptotic limit). The spin-integrated photoemission spectra in Fig. 1 show the development of the valence band states for increasing thickness of the Cu film. These data have been measured for normal electron emission. This geometry probes states with initial state $k_{\parallel}=0$, where $k_{\parallel}$ is the component of the wave vector parallel to the surface plane. The sp-derived Cu states give rise to new and well-defined structures easily observed above the Cu $3d$ band edge, within 2 eV binding energy from the Fermi level.

The energy dispersion of the sp-derived Cu states as a function of film thickness, shown in Fig. 1, resembles that of quantum-well states. It can be satisfactorily modeled assuming discretization of bulklike states due to the finite size of the layer, as proposed by Ortega *et al.*[6] In Fig. 2(a) we compare the dependence of the sp-state binding energy on the film thickness with the predictions based on the bulk band structure. Above a film thickness of about 5 monolayers the experimental data follow rather closely the expectations of a simple quantum-well picture. Our results are similar to those reported by Ortega *et al.*[6] and by Garrison *et al.*[8] Noble metal films display a similar development of sp-derived quantum-well states also on other magnetic[6] and nonmagnetic substrates.[13]

The capability of quantum-well states to mediate the indirect exchange interactions in multilayers depends on their coupling to the magnetic substrate. The interface boundary conditions and the hybridization with substrate levels will in general be different for states of opposite spin. For this reason the electronic structure of the thin film might develop spin-polarized bands, for which the spin degeneracy has been lifted. We have experimentally established that quantum-well states of Cu on Co(100) are magnetically polarized, by measuring the spin polarization of the photoelectrons. The results of the spin-resolved measurements are presented in Fig. 3, for several film thicknesses. In correspondence to the quantum-well states discussed above, the spectra exhibit spin-polarized spectral features. The quantum-well states shown in Fig. 3 are spin-polarized up to a Cu thickness of at least 10 monolayers. They are predominantly of spin-down (minority) character. Furthermore, weak spin-up (majority) states appear, separated by an exchange splitting (in average 0.2 eV) from the more intense spin-down states.

Pairs of spin-up and spin-down features gradually shift with increasing coverage to lower binding energy [see Fig. 2(b)]. By varying the film thickness, polarized states at a given energy periodically appear and disappear. This causes a modulation of the photoemission intensity [Fig. 2(c)] and of the spin polarization at the Fermi level [Fig. 2(d)]. Both have a similar periodicity, with an oscillation period of 5–6 monolayers, corresponding to the main RKKY wave vector

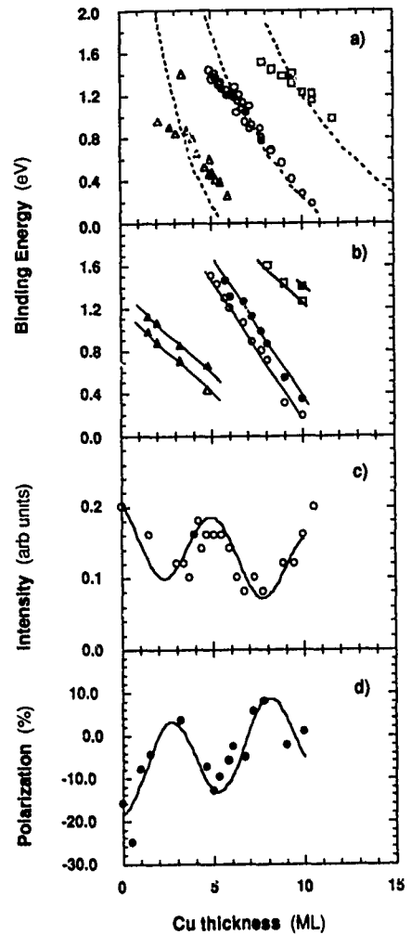

FIG. 2. (a) Binding energy of the Cu sp-derived states as a function of the film thickness, as determined from spin-integrated photoemission spectra. (b) Binding energy of the spin-polarized Cu-derived states as a function of film thickness, as determined from spin-resolved spectra. (c) Intensity at the Fermi level as a function of film thickness, after subtraction of the substrate emission. (d) Spin polarization at the Fermi level as a function of film thickness.

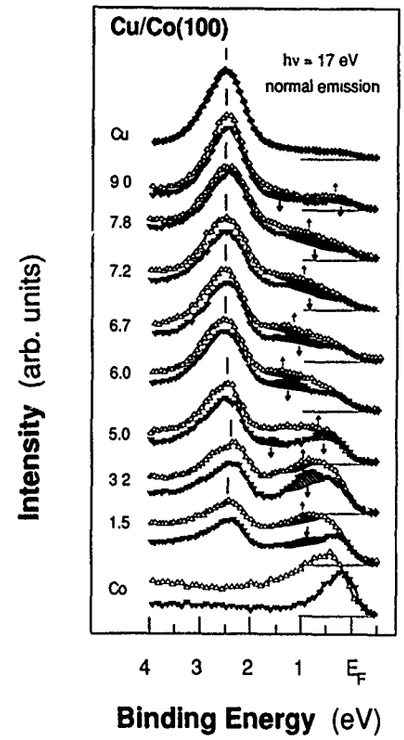

FIG. 3. Spin- and angle-resolved photoemission spectra of Cu on Co(100). The spectra are measured for normal emission with 17 eV photon energy, as in Fig. 1. Open symbols correspond to spin-up emission, full symbols to spin-down emission.

along the ⟨100⟩ direction. In brief, the results directly show that the interaction with the magnetic substrate induces a spin polarization on the Cu sp states. These levels are spin-split into two separated sub-bands, both displaying a dispersion close to that expected for quantum-well states.

It should be noticed that quantum-well states, intended as discrete states strictly confined within the overlayer, can only form in correspondence to a band gap in the substrate electronic structure. In Co(100) there is no band gap for states near E_F (Ref. 14) with $k_\parallel=0$. A complete confinement within the overlayer should thus not be expected, because of the coupling to degenerate bulk states (of proper symmetry) of the substrate. In fcc Co these states are the strongly dispersive Δ_1 subbands of both spin characters, which cross the Fermi level along the Γ-X direction. A Δ_1 symmetry-projected energy gap of the spin-down bands is located in fcc Co between 1 and 2 eV binding energy. In fact, in this energy region most intense quantum-well structures are observed in the spin-down channel. However, the reflectivity due to the interface may also partially confine within the film sp states that are degenerate with the substrate levels.[6] In this way, narrow resonance states[15] rather than discrete quantum-well states appear in the overlayer. It is thus ultimately a departure from an ideal quantum-well behavior that determines the role of the sp states in the magnetic coupling through Cu(100). The coupling to the substrate polarizes the s-derived states but at the same time reduces their degree of confinement within the overlayers.

For a comprehensive understanding of the polarization effects in the Cu films the coupling to the Co states will still have to be analyzed experimentally and theoretically in more detail. For example, the role of (modified) surface states and interface states localized near the magnetic substrate still needs to be examined. In the case of Ag on Fe(100),[12] Pd on Fe(100),[5] and Fe on Pd(100),[16] it has been shown that interface states can convey the magnetization in nonmagnetic layers. Furthermore, recent measurements of the x-ray magnetic circular dichroism at the Cu $L_{2,3}$ edge in multilayers have detected an induced moment in the Cu $3d$ levels.[17] This moment is largely localized at the interface but it might also present weak long-range oscillation. On the basis of tight binding calculations Garrison *et al.*[8] suggest that the polarization of the quantum well states results from the hybridization between the Cu s- and d-derived states. Recent first principle calculations,[15] which emphasize the scattering nature of quantum well states using a Korringa–Kohn–Rostoker (KKR)–Green's function method, account for their

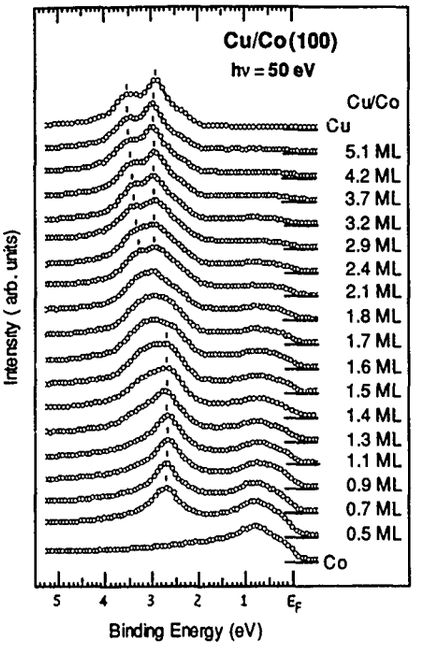

FIG. 4. Angle resolved photoemission spectra of Cu films on Co(100). The data are obtained with 50 eV photon energy for normal electron emission. The development of the Cu 3*d* bands, below 2 eV binding energy, is displayed as a function of the film thickness.

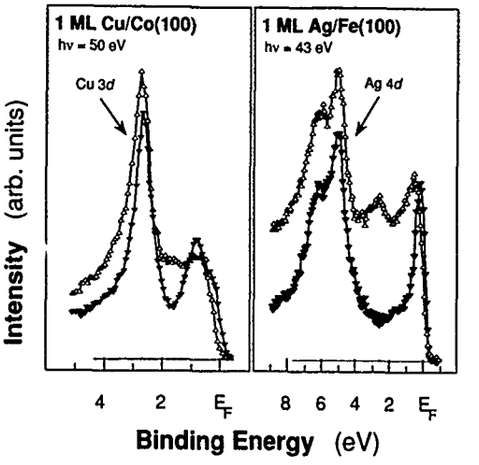

FIG. 5. Spin- and angle-resolved photoemission spectra of a Cu monolayer on Co(100), (left panel), and an Ag monolayer on Fe (100). Open symbols correspond to spin-up emission, full symbols to spin-down emission. The noble metal *d* states appear as intense features, at binding energies below 2 eV in Cu and below 4 eV in Ag. The strongly polarized emission closer to the Fermi level is mainly due to the magnetic 3*d* states of the substrate.

dispersion as a function of Cu thickness and for a small spin splitting between spin-up and spin-down states. These calculations predict a very small exchange splitting for the Cu 3*d* bands, in accord with the weak spin-dependence of the Cu 3*d* emission in the photoemission spectra of Fig. 3.

The experimental results presented above show that polarized electronic states related to the long range exchange coupling in multilayer systems, either of *s* or *d* character, can be directly investigated by spectroscopic methods. Further photoemission studies are now in progress in order to assess the connection between spectroscopically accessible conduction band properties (such as the Fermi surface and its modification in ultrathin layers) and the magnetic coupling phenomena. We present in the next section new results for the low coverage limit (i.e., noble metal films 1–2 monolayers thick), where the hybridization with the magnetic interface is the determining factor.

B. Cu on Co(100) and Ag on Fe(100): Approaching the monolayer limit

Deviations from a simple quantum-well behavior, based on the quantization of bulklike states, or from the RKKY scheme are expected to become evident for small thicknesses of the nonmagnetic film. Approaching the monolayer limit, the electronic structure can be strongly modified by the interaction with the substrate as well as by the reduced atomic coordination. This is manifested for example in the photoemission spectra of the relatively highly localized Cu 3*d* states up to about 4 ML.

The spectra in Fig. 4 display the developments of the Cu 3*d* states with increasing coverage, for initial states with $k_{\parallel}=0$ (the $\bar{\Gamma}$ point of the two-dimensional Brillouin zone). Similar results are obtained at other emission angles and photon energies. Up to 1 ML coverage we obtain a single narrow peak. With the second monolayer the spectra develop a broader structure still without a corresponding structure in the Cu bulk spectra. At 1 and 2 ML coverages the Cu 3*d* states do not show any dispersion with varying photon energy, as expected for two-dimensional states. With the formation of the third monolayer the Cu 3*d* bands begin to develop the spectral features of three-dimensional Cu. Only with the fourth monolayer the binding energy of most Cu 3*d* states becomes close to that of the bulk, although the (relative) spectral intensities still differ in some cases considerably from the bulk case.

In order to test the importance of the spin dependent hybridization with the magnetic substrate in determining the evolution of the Cu 3*d* bands, we have measured the monolayer spectrum also with spin resolution. The results, shown in Fig. 5, indicate that the exchange splitting of those 3*d* states is smaller than 0.1 eV. We also show in Fig. 5 the spin-polarized spectrum corresponding to the $\bar{\Gamma}$ point for an Ag monolayer on Fe(100). Similarly to the case of Cu, the data suggest that these Ag 4*d* states, between 4 and 7 eV binding energy, exhibit only a very small exchange splitting, of less than 0.1 eV. Although other point in *k* space might present a larger splitting, calculations on noble metal monolayers and interfaces coupled with magnetic materials[4,17] show that it should not exceed a few tenths of an eV. For this reason, we believe that the development of the 3*d* spectral features described above reflects primarily a transition from quasi-two-dimensional bands to a bulklike electronic structure.

The convergence to a bulklike band structure can be expected to occur at even larger thicknesses for the extended *sp*-conduction states. Indeed, as mentioned already in the previous section, below about 5 ML the experimental bind-

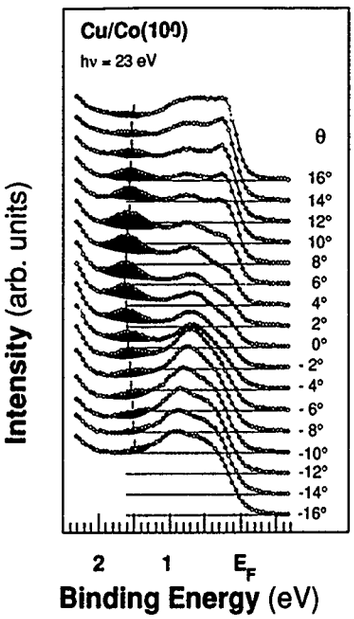

FIG. 6. Angle-resolved spectra of 2 Cu monolayers on Co(100), probing the dispersion along the $\bar{\Gamma}$-$\bar{X}$ direction. The spectra are measured at 23 eV for various emission angles. The noble metal induced features are indicated by gray shadowed areas.

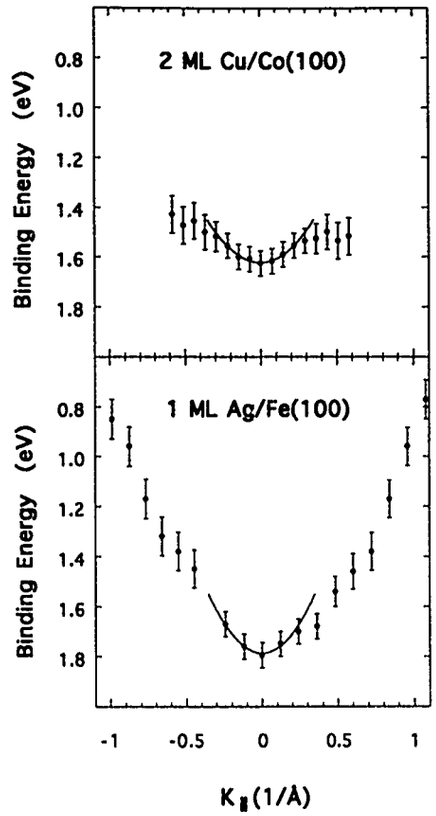

FIG. 8. Experimentally determined band dispersion as a function of the parallel wave vector for 2 Cu monolayers on Co (100) (upper panel) and 1 Ag monolayer on Fe(100) (lower panel). The dispersion is measured along the $\bar{\Gamma}$-$\bar{X}$ symmetry direction. The solid lines indicate free electron-like dispersion corresponding to an electron effective mass of 2.7 (upper panel) and 2 (lower panel).

ing energies of the *sp* states differ systematically from those expected for quantized bulklike states, in Cu on Co(100)[6,7] and in other noble metal films.[6] The discrepancy can originate from two effects: (i) in the monolayer regime the bands are altered by the reduced atomic coordination and lowered symmetry, as seen above for the *d* states, (ii) the hybridization with the substrate states further modifies the overlayer states in a way that depends on the spin, wave vector and symmetry of the band. We examine here how the *sp*-derived states form at low coverages two-dimensional magnetic bands, which eventually develop the simple behavior of quantum-well states in thicker films. We have studied the system Cu on Co (100) as well as an Ag monolayer on Fe (100).

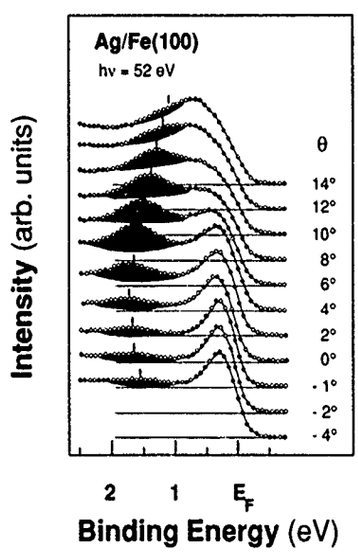

FIG. 7. Angle-resolved spectra of an Ag monolayers on Fe(100), probing the dispersion along the $\bar{\Gamma}$-$\bar{X}$ direction. The spectra are measured at 52 eV for various emission angles. The noble metal induced features are indicated by gray shadowed areas.

The spectra in Figs. 6 and 7 show the band dispersion for an Ag monolayer on Fe(100), and for two Cu monolayer on Co(100) along the $\bar{\Gamma}$-$\bar{X}$ symmetry direction. The gray shadowed areas indicate the noble metal-induced features which appear superimposed to the 3*d* emission of the substrate. In both cases the features we have followed correspond to the first and most intense spectral structure induced by the overlayer, apart from the strong *d*-emission at higher binding energy. For Cu on Co the peak at 1.6 eV is prominent in the 23–30 eV photon energy spectra but hardly discernible at lower photon energy. The *s*-related character of these states is indicated by tight binding calculations.[8,12] In both cases spin-resolved photoemission reveals that these structures have predominantly spin-down character.[8,11,12] These states are thus well suited for studying the preasymptotic limit as they can be looked upon as the precursor of spin-polarized quantum-well states. We do not detect a dispersion of these features upon changing the photon energy, consistently with a two-dimensional character. By varying the emission angle we can determine the dispersion of these bands as a function

of the parallel wave vector $\mathbf{k}_{\parallel}$. The initial state wave vector is given by the projection on the surface plane of the photoelectron momentum as measured outside the solid.

The experimentally determined band dispersion in Fig. 8 summarizes the results presented above. The spin-down band between 1 and 2 eV induced by the noble metal display the expected symmetric behavior with respect to the center of the Brillouin zone. The dispersion of these bands is considerably weaker than for nearly free-electron-like states. Assuming a simple parabolic dispersion in the proximity of the zone center $\bar{\Gamma}$ we obtain an electron effective mass of about 2 for the Ag bands and about 2.7 for the Cu-derived bands. This strong departure from a free-electron-like dispersion becomes in both cases even more evident away from $\bar{\Gamma}$. This behavior indicates the importance at low coverage of the hybridization of Cu 4*s* states with other and more localized levels. For an Ag monolayer on Fe(100) tight binding band structure calculations identify the state at 1.7 eV as a spin-polarized interface states. Recent *ab initio* calculations describe well the experimental dispersion,[11] showing that a true spin polarized interface states derived from the Ag 5*s* levels is shared by both the constituents. Consistently with the experimental results reported above, the calculated bands[11] present an increasingly admixture with Fe 3*d* states on moving from $\bar{\Gamma}$-$\bar{X}$. In summary the *s*-derived states in the low thickness limits show a significant departure from a simple quantum-well model. This is not only due to the reduced dimensionality of the system but also to the hybridization with the magnetic states of the substrate.

IV. CONCLUSIONS

By spin- and angle-resolved photoemission we have investigated the electronic structure of Cu on Co(100) and Ag on Fe(100), in order to clarify the origin of the indirect exchange coupling through noble metals. We find that the *sp*-derived electronic states of the noble metals are spin-polarized upon contact with the magnetic materials. For film thicknesses above a few monolayers, a quantum-well picture, based on the quantization of bulklike states, describes the development of the *sp* states. In the low coverage regime, the conduction electron bands are instead strongly modified by hybridization with the states of the magnetic substrate.

Recent progress in the theory of interlayer exchange coupling (invited)

P. Bruno[a)]

Recent progress in the theory of interlayer exchange coupling is presented. The interlayer coupling is described in terms of quantum interferences in the spacer layer, due to reflections of Bloch waves on the spacer boundaries. This approach is used to discuss (i) the coupling variation with respect to *ferromagnetic layers thickness*, and (ii) the coupling across a *nonmetallic* spacer layer.

I. INTRODUCTION

In the past few years, the intense research activity on interlayer exchange coupling, both experimental and theoretical, has been essentially focussed on the oscillations of the interlayer coupling with respect to *spacer thickness*, in systems with *metallic* spacer layers.[1,2] Recently, the interest in this field has been renewed by (i) the theoretical prediction[3,4] and experimental confirmation[5,6] of oscillations of the coupling with respect to *ferromagnetic layers thickness*, and (ii) the discovery of interlayer exchange coupling across *nonmetallic* spacer layers,[7] which, furthermore, may be *thermally induced*[8] or *photoinduced*.[9,10]

In this article, I address the above mentioned new aspects of the problem of interlayer exchange coupling. This study relies on a formalism developed previously,[11] in which the interlayer coupling is described in terms of quantum interferences in the spacer, due to reflections of Bloch waves on the spacer boundaries. This approach, which has been rederived subsequently by Stiles,[12] has the virtue of being physically transparent, and also provides a suitable starting point for quantitative calculations, either for models, or for realistic systems. A heuristic presentation of this approach is given in Sec. II.

As pointed out in Ref. 4, it becomes almost obvious, in the light of the "quantum interferences" formulation, that one may expect oscillations of the coupling versus ferromagnetic layers thickness, as a consequence of the interferences associated with the multiple internal reflections in a magnetic layer of finite thickness, in analogy with the reflection oscillations in an optical Pérot–Fabry cavity. This problem is discussed in detail in Sec. III.

In contrast to the important theoretical literature devoted to interlayer coupling across metal spacer, the magnetic coupling across insulators has attracted very little attention on the theoretical point of view. A notable exception is Slonczewski's model of coupling, at $T=0$, through a tunneling barrier:[13] the coupling, in this case is non-oscillatory, and decays exponentially with spacer thickness. In a recent paper,[14] I discussed this problem within the quantum interferences approach: at $T=0$, one recovers the results of Slonczewski; on the other hand, the coupling is found to *increase* with increasing temperature, in contrast to the metal spacer case. This study is presented in Sec. IV.

In view of pedagogical clarity, the free-electron model will be used in Secs. III and IV. For this simple case, the calculations can be performed analytically, thus providing a physically transparent illustration of the various aspects of the problem. The model is sketched in Fig. 1: the zero of energy is taken at the bottom of the majority band of the ferromagnetic layers; the potential of the minority band is given by the exchange splitting Δ, while the spacer, of thickness D, has a potential equal to U. The ferromagnetic layers, F_A and F_B, have a thickness L ($L=\infty$ stands for semiinfinite magnetic layers), and their magnetizations are at an angle θ with respect to each other. According to the position of the Fermi level, this model describes the case of a metallic spacer (for $\epsilon_F > U$), or of an insulating spacer (for $\epsilon_F < U$).

II. QUANTUM INTERFERENCES AND INTERLAYER EXCHANGE COUPLING

In this section, I shall present a heuristic presentation of the interlayer coupling in terms of quantum interferences in the spacer layer; the emphasis will be on physical transparency rather than on mathematical strictness.

Inside the paramagnetic layer, a conduction electron experiences essentially the same potential as in the bulk material; deviations from the bulk potential are confined to the interface regions, and, of course, to the regions occupied by the ferromagnetic material. Thus, the electrons propagate through the spacer like in the bulk material; the effect of potential deviations as they encounter the interface with the ferromagnetic material make them being (partly) reflected towards the paramagnet. Because of the spin polarization of the ferromagnetic material, the potential deviation at the interface is spin dependent, and so is the reflection coefficient.

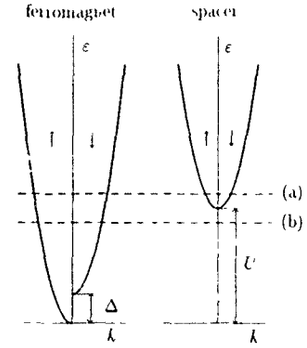

FIG. 1. Sketch of the free-electron model; the dashed line indicates the position of the Fermi level, (a) for the metallic spacer case, (b) for the insulating spacer case.

Since the in-plane translational invariance is maintained, the in-plane component $\mathbf{k}_\parallel$ of the wave vector is a good quantum number, i.e., it is conserved under reflection. For an incident electron of wave vector $\mathbf{k}^i=(\mathbf{k}_\parallel,k_\perp)$, the reflected wave vector is $\mathbf{k}^r=(\mathbf{k}_\parallel,-k_\perp)$ and the corresponding complex reflection coefficient for spin parallel (antiparallel) to the magnetization in the ferromagnet is $r^{\uparrow(\downarrow)}$; the module of the reflection coefficient gives the amplitude of the reflected wave, while its argument ϕ gives the phase shift due to the reflection. We also define

$$\bar{r}\equiv\frac{r^\uparrow+r^\downarrow}{2} \quad \text{and} \quad \Delta r\equiv\frac{r^\uparrow-r^\downarrow}{2}, \tag{1}$$

respectively, the spin-average and spin-asymmetry of the reflection coefficients.

In the paramagnetic spacer, the electrons are reflected on both interfaces (F_A and F_B), so that interferences take place due to the multiple reflections. Let us consider a wave of vector $\mathbf{k}=(\mathbf{k}_\parallel,k_\perp)$, with $k_\perp>0$; the phase change of the wave function after a round trip in the spacer (one reflection on F_A and one reflection on F_B) is

$$\phi_{AB}=2k_\perp D+\phi_A+\phi_B; \tag{2}$$

if the interferences are constructive (respectively, destructive), i.e., if

$$\begin{aligned}\phi_{AB}&=2n\pi\\&=(2n+1)\pi \ \text{(respectively)},\end{aligned} \tag{3}$$

with n integer, the density of states is enhanced (respectively, lowered) in the spacer layer. Taking these interferences into account, the wave function in the spacer may be written as

$$\psi(\mathbf{r})\sim e^{i\mathbf{k}_\parallel\cdot\mathbf{r}_\parallel}e^{ik_\perp z}(1+|r_Ar_B|e^{i(2k_\perp D+\phi_A+\phi_B)}), \tag{4}$$

where higher order interference terms have been neglected. The corresponding contribution to the ($\mathbf{k}_\parallel$ projected) density of states is

$$n(\mathbf{k}_\parallel,\epsilon)\sim\frac{dk_\perp}{d\epsilon}\int_0^D dz|\psi|^2, \tag{5}$$

where the integral gives the contribution of one state $(\mathbf{k}_\parallel,k_\perp)$ and the prefactor $dk_\perp/d\epsilon$ gives the number of states in an energy interval $[\epsilon,\epsilon+\delta\epsilon]$.

Here, we are interested essentially in the part of $n(\mathbf{k}_\parallel,\epsilon)$ which is associated with the interferences, i.e.,

$$\begin{aligned}\Delta n(\mathbf{k}_\parallel,\epsilon)&\sim 2D\frac{dk_\perp}{d\epsilon}|r_Ar_B|\cos(2k_\perp D+\phi_A+\phi_B)\\&\sim\mathrm{Im}\left(2iD\frac{dk_\perp}{d\epsilon}r_Ar_Be^{2ik_\perp D}\right).\end{aligned} \tag{6}$$

The total change of in the density of states per unit area is obtained by summing over in-plane wave vectors and over the spin, yielding

$$\Delta n_F(\epsilon)\sim\mathrm{Im}\int d\mathbf{k}_\parallel 2iD\frac{dk_\perp}{d\epsilon}(r_A^\uparrow r_B^\uparrow+r_A^\downarrow r_B^\downarrow)e^{2ik_\perp D}, \tag{7}$$

for the ferromagnetic configuration, and similarly,

$$\Delta n_{AF}(\epsilon)\sim\mathrm{Im}\int d\mathbf{k}_\parallel 2iD\frac{dk_\perp}{d\epsilon}(r_A^\uparrow r_B^\downarrow+r_A^\downarrow r_B^\uparrow)e^{2ik_\perp D}, \tag{8}$$

for the antiferromagnetic configuration.

The interlayer exchange coupling per unit area (at $T=0$) may be expressed as

$$E_F-E_{AF}\equiv\int_{-\infty}^{\epsilon_F}(\epsilon-\epsilon_F)[\Delta n_F(\epsilon)-\Delta n_{AF}(\epsilon)]d\epsilon; \tag{9}$$

integrating by parts, we get for the interlayer exchange coupling (for large D)

$$\begin{aligned}E_F-E_{AF}&\sim-\mathrm{Im}\int d\mathbf{k}_\parallel\int_{-\infty}^{\epsilon_F}d\epsilon(r_A^\uparrow r_B^\uparrow+r_A^\downarrow r_B^\downarrow-r_A^\uparrow r_B^\downarrow\\&\quad-r_A^\downarrow r_B^\uparrow)e^{2ik_\perp D}\\&\sim-\mathrm{Im}\int d\mathbf{k}_\parallel\int_{-\infty}^{\epsilon_F}d\epsilon\,4\Delta r_A\Delta r_Be^{2ik_\perp D}.\end{aligned} \tag{10}$$

As appears clearly from Eq. (10), the coupling depends on (i) the wave vectors $k_\perp$ in the spacer layer, and (ii) the spin-asymmetries Δr_A and Δr_B of reflection coefficients at the paramagnetic-ferromagnetic interfaces; the former determine the oscillation periods of the coupling, while the latter determine its strength.

So far I have implicitely considered that the incident and reflected waves are usual propagative Bloch waves (with $k_\perp$ real); these are the states which are allowed in bulk materials. However, in a slab of finite thickness, evanescent states [with $\mathrm{Im}(k_\perp)$ nonvanishing] are also present and contribute to the density of states. Thus, evanescent states contribute to the coupling in Eq. (10) on an equal footing; in particular, they are found in gaps of the bulk band structure. The rôle played by these states will be discussed in Sec. IV.

An exact derivation, using Green's functions formalism, yields, for the interlayer coupling energy per unit area,[11]

$$E_{AB}(\theta)=J_0+J_1\cos\theta+J_2\cos^2\theta+\cdots \tag{11}$$

with the Heisenberg coupling constant

$$\begin{aligned}J_1=&-\frac{1}{4\pi^3}\mathrm{Im}\int d^2\mathbf{k}_\parallel\int_{-\infty}^{+\infty}d\epsilon\,f(\epsilon)\\&\times\frac{2\Delta r^2e^{2ik_\perp D}}{1-2\bar{r}^2e^{2ik_\perp D}+(\bar{r}^2-\Delta r^2)^2e^{4ik_\perp D}},\end{aligned} \tag{12}$$

where $f(\epsilon)$ is the Fermi–Dirac distribution, and where the indices A and B have been dropped, since $r_A^{\uparrow(\downarrow)}=r_B^{\uparrow(\downarrow)}$.

III. VARIATION OF THE COUPLING WITH RESPECT TO MAGNETIC LAYERS THICKNESS

I consider here the case of ferromagnetic layers of finite thickness L. For simplicity, I shall restrict myself to the case of a metallic spacer; more precisely, I take $U=0$; thus, the magnetic layer is *transparent* for electrons of spin parallel to the majority spins, i.e., $r^\uparrow=0$ and $\bar{r}=-\Delta r=r^\downarrow/2$.

In the case of a layer of finite thickness, like in Pérot–Fabry cavity, all the waves associated with the multiple re-

flections inside the magnetic layer contribute to the net reflection coefficient. The summation is easily carried out, and one gets

$$r^{\downarrow}=r_{\infty}^{\downarrow}\frac{1-\exp[2ik_{\perp}^{\downarrow}L]}{1-r_{\infty}^{\downarrow 2}\exp[2ik_{\perp}^{\downarrow}L]}, \tag{13}$$

where $k_{\perp}^{\downarrow}$ is the minority-spin wave-vector in the magnetic layer, and $r_{\infty}^{\downarrow}$ the reflection coefficient for a semi-infinite magnetic layer. Clearly, the variation of $r^{\downarrow}$ with respect to L is oscillatory or exponential, according to the nature—propagative or evanescent—of the state of wave vector $k_{\perp}^{\downarrow}$. The interlayer coupling is governed essentially by the states lying at the Fermi level. Thus, if $k_F^{\downarrow}$ is real, one can expect oscillations of the interlayer coupling vs. magnetic layers thickness to show up. The oscillations are due to the quantum interferences inside the magnetic layers: when the interferences are constructive (respectively, destructive), the coupling strength is enhanced (respectively, reduced). Below, I consider only the former case, i.e., $k_F^{\downarrow}$ real.

In the limit where both L and D are large, the expression of the coupling (at $T=0$) reduces to[4]

$$J_1=\frac{1}{4\pi^2D^2}\frac{\hbar^2k_F^2}{2m}\,\mathrm{Im}\left\{\frac{r_{\infty}^{\downarrow 2}}{2}e^{2ik_FD}\times\left[1-2(1-r_{\infty}^{\downarrow 2})\left(1+\frac{k_F}{k_F^{\downarrow}}\frac{L}{D}\right)^{-2}e^{2ik_F^{\downarrow}L}\right]\right\}. \tag{14}$$

Clearly, the interlayer exchange coupling oscillates versus L, with a period equal to $\pi/k_F^{\downarrow}$. The amplitude of these oscillations decays essentially as L^{-2}. To illustrate this behavior, I have performed numerical calculations for the free-electron model with $\epsilon_F=7.0$ eV, $U=0$, and $\Delta=1.5$ eV; these calculations use the exact expression (12), not the asymptotic one (14). The results are displayed in Fig. 2: the coupling variation versus magnetic layer thickness L, for several value of the spacer thickness D. The oscillatory behavior of period $\pi/k_F^{\downarrow}$, and the L^{-2} decay appear clearly. A striking feature is that, in contrast to the oscillations of J_1 vs D, the oscillations are not necessarily around zero: instead, J_1 may oscillate around a positive, or a negative value, depending on the choice of the spacer thickness D. This point is also obvious from Eq. (15).

On the other hand, for large D and small L, one has

$$J_1=\frac{1}{4\pi^2D^2}\frac{\hbar^2k_F^2}{2m}\,\mathrm{Im}(-2k_F^{\downarrow 2}L^2r_{\infty}^{\downarrow 2}e^{2ik_FD}). \tag{15}$$

The fact that the coupling varies like L^2 at low magnetic layers thickness is obvious from the analogy with optics: the reflection coefficient for a thin layer is proportional to its thickness.

Until recently, it was generally believed that the coupling is essentially independent of the magnetic layers thickness. This point has been studied experimentally in the case of Co/Cu/Co(001) by Qiu *et al.*,[15] who found no dependence of the coupling versus Co thickness; however, only three different Co thicknesses have been used in this study. On the theoretical point of view, oscillations of the coupling versus magnetic layers thickness have been first reported by Barnaś[3]

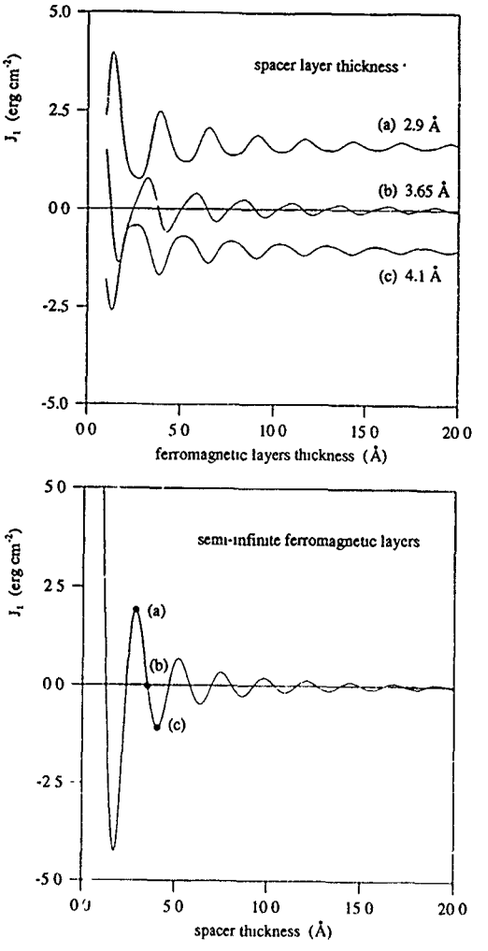

FIG. 2. Interlayer exchange coupling constant J_1, calculated as a function of the spacer thickness D, for semi-infinite ferromagnetic layers (lower panel), and as a function of the ferromagnetic layers thickness L, for various values of the spacer thickness D (upper panel).

from numerical calculations for the free-electron model. The explanation of this behavior on the basis of the quantum interferences picture has been given in Ref. 4; in this article, I also estimated the oscillation period versus Co thickness in Co/Cu/Co(001) to be about 3.5 atomic layers (ALs).

The predictions of Ref. 4 have been confirmed recently by Bloemen *et al.*,[5] who succeeded in observing oscillations of the coupling versus Co thickness in Co/Cu/Co(001); the observed period is about 3.5 ALs, in very good agreement with the predicted one. Further confirmation has been given by Okuno and Innomata,[6] who observed oscillations of interlayer coupling versus Fe thickness in Fe/Cr(001) multilayers.

IV. METALLIC VERSUS INSULATING SPACER

In this section, I discuss the coupling behavior, in particular its spacer thickness and temperature dependence, for a nonmetallic spacer ($\epsilon_F<U$), in comparison with the case of a metallic spacer ($\epsilon_F>U$). For simplicity, I take $L=\infty$.

Because of the abrupt variation of the Fermi–Dirac distribution at the Fermi energy, the interlayer coupling is determined by the neighborhood of the Fermi level. Thus, the

nature of the states present at the Fermi level controls the physical behavior of the coupling. In the case of a metallic spacer, one has propagative states at Fermi energy, and this leads to the oscillatory character of coupling vs. spacer thickness. For an insulating spacer, on the other hand, the states with Fermi energy are evanescent waves, so that we expect a monotonic exponential decay of the interlayer coupling with spacer thickness.

In the limit of large spacer thickness and low temperature, Eq. (12) becomes[14]

$$J_1=\frac{1}{4\pi^2}\frac{\hbar^2k_F^2}{mD^2}\,\mathrm{Im}(\Delta r^2 e^{2ik_FD})\frac{2\pi k_BTDm/\hbar^2k_F}{\sinh(2\pi k_BTDm/\hbar^2k_F)} \tag{16}$$

with

$$k_F=[2m(\epsilon_F-U)/\hbar^2]^{1/2}, \tag{17a}$$

$$k_F=i[2m(U-\epsilon_F)/\hbar^2]^{1/2}, \tag{17b}$$

respectively, for a metallic and an insulating spacer.

Of course, the coupling behavior is completely different in both cases. While it is oscillatory for a metal spacer, it decreases exponentially with spacer thickness in the insulator case. Another striking difference concerns the temperature dependence, which is given by the last factor in Eq. (16). For a metal spacer the coupling decreases with increasing temperature.[2] On the other hand, when we consider the insulating spacer case, where k_F is imaginary, the exchange coupling *increases* with temperature for an insulating spacer, because $\sinh(ix)/ix \equiv \sin(x)/x$ is an increasing function. Physically, this behavior may be understood easily: when the temperature increases, the contribution of states below the Fermi level is lowered, at the expense of states above the Fermi level; since the penetration length of the latter is larger than the one of the former, the exchange coupling is thereby enhanced.

To illustrate the above results more quantitatively, we have performed numerical calculations of the exchange coupling for the free electron model, with $\epsilon_F=10.0$ eV, $\Delta=1.5$ eV, and $U-\epsilon_F=0.1$ eV; the calculation uses the exact expression (12), not the asymptotic result (16). The results are displayed on Fig. 3. With the above choice of parameters, the coupling at large spacer thicknesses is antiferromagnetic ($J_1>0$). One clearly observes the strong temperature increase of the coupling; as expected from Eq. (16), the relative thermal variation increases with increasing thickness.

One should be careful when comparing the results with experimental observations of coupling across no-metallic spacers: indeed, the latter concern materials that are disordered or even amorphous, whereas the theory presented here pertains to ordered systems; the importance of disorder for the *thermally induced* coupling remains to be clarified. Nevertheless, the finding of a positive temperature coefficient for the exchange coupling through an insulating spacer provides a plausible explanation for the experimental observations of *thermally induced* exchange coupling.[8] Note that the latter result is not restricted to the free-electron case, and may be shown to hold for any insulating spacer material.

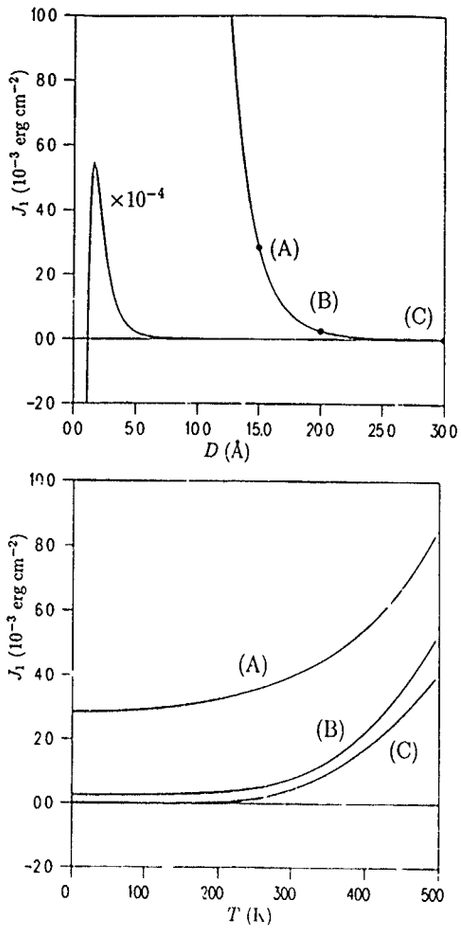

FIG. 3. Calculated interlayer exchange coupling across an insulating spacer; (upper panel) exchange coupling versus spacer thickness at $T=0$; (lower panel) exchange coupling vs. temperature for various spacer thickness, corresponding to the solid points: (A) 15.0 Å, (B) 20.0 Å, and (C) 30.0 Å.

V. CONCLUDING REMARKS

In this article, I have discussed various new aspects of the problem of interlayer exchange coupling, on the basis of the quantum interference approach, is which the coupling is expressed in terms of reflection coefficients at the boundaries of the spacer layer.

This approach provides a physically transparent description of the phenomenon of interlayer exchange coupling. When applied to simple models, such as the free-electron model, the calculations can be performed almost completely analytically.

I have shown that the interlayer coupling me be expected to exhibit oscillations versus ferromagnetic layers thickness, a prediction which has been confirmed recently by experiments. For the case of an insulating spacer, the expression of the coupling is formally similar to the metallic spacer case; however, the evanescent character of the states with Fermi energy leads to a completely different physical behavior: in contrast to the metal spacer case, the coupling has a monotonic exponential decay with respect to spacer thickness, and increases with temperature. This result provides a plausible explanation for recent experimental observations.

Exchange anisotropy in films, and the problem of inverted hysteresis loops

Amikam Aharoni[a)]
Department of Electronics, Weizmann Institute of Science, 76100 Rehovoth, Israel

The inverted hysteresis loop is claimed to be possible, in an exchange-coupled bilayer, when a magnetically soft material is affected by the demagnetizing field of the hard material. These demagnetizing fields are caused by the charge on the surfaces, neglected in all the theories that assume a strictly one-dimensional structure, in an *infinite* material. For these one-dimensional models, an analytic solution is presented, which reduces the computation from a numerical integration of a set of differential equations to the solution of an *algebraic*, transcendental equation (which contains elliptic functions) for fitting only the boundary conditions. It may then be feasible to introduce at least an approximation for the demagnetizing effect of the surfaces in a finite sample.

I. INTRODUCTION

Inverted hysteresis loops have been observed[1,2] in some exchange-coupled multilayers. In the decreasing part of such loops the magnetization becomes negative when the applied field is still positive, while in the increasing part the magnetization becomes positive when the applied field is still negative (see Fig. 2). No explanation is known for this unusual phenomenon. The attempt[1,2] to relate it only to the exchange coupling at the interface failed, in the sense that the theory did not produce anything similar to the observed loops.

Unlike the exchange coupling, which acts on the boundary layer only, magnetostatic interaction between the layers acts on the whole volume of the film, and is thus more effective and more likely to produce inverted loops. However, the magnetostatic interaction is complicated and difficult to take into account, and is just neglected in most theoretical studies. To illustrate the complexity, two cases of such exchange-coupled layers are shown schematically in Fig. 1.

In case (a) the magnetic field is in the film plane, and the magnetization of the hard component, A, is pointing to the right. A simple-minded calculation assumes an *infinite* film, with no demagnetizing effect. However, these films do end *somewhere* and there is a charge on that surface. This charge (shown schematically as the pluses) creates a field (shown schematically by the two field lines), which points to the left when the applied field is to the right. The field acting on the soft material, B, is the difference between these fields, and can be negative in a positive applied field.

In case (b) the applied field, and the magnetization in the film, are pointing upwards. There should be no demagnetizing effects besides the overall demagnetization, which is easy to take into account. However, if the films are not continuous, and one material "penetrates" through the other one, a surface charge can be created, as seen in Fig. 1, and the effect is the same as in case (a).

These effects are not easy to estimate, because they depend on the fine details of the layer structure; but they are *not* negligible, because the magnetostatic self-energy is usually very large. A rather crude theory will be given in Sec. II, which demonstrates the main physics of the present suggestion for the origin of the inverted hysteresis loop. A method for advancing to a more realistic approximation will be proposed in Sec. III.

II. SIMPLE THEORY

The earliest theory[3] of exchange coupling in a geometry of an infinite slab used an oversimplified picture of the CoO layer as being infinitely hard, so that the direction of its magnetization could not be changed by any applied field. The softer, cobalt, layer was assumed to be sandwiched between such CoO layers, and the coupling to these layers gave the boundary conditions for the energy minimization. For this model the differential equation could be solved analytically, and the reduced magnetization in the field direction was shown[3] to be

$$j=\langle M_H\rangle/M_s=-1+2E(k)/K(k), \tag{1}$$

where K and E are the complete elliptic integrals of the first and second kind, respectively, and k is a parameter, related to the reduced applied field,

$$h=H/(2\pi M_s), \tag{2}$$

by

$$-\pi S^2 h=[K(k)]^2, \quad S=aM_s/\sqrt{A}. \tag{3}$$

Here $A=C/2$ is the exchange constant, and a is the Co film thickness.

Two changes are made in this theory for using it here.

(1) In a sufficiently large field the CoO layer reverses its

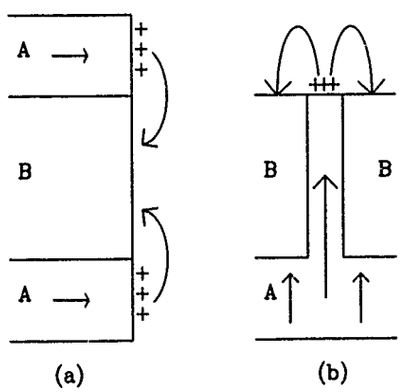

FIG. 1. Schematic representation of a soft magnetic layer, "B" being demagnetized by the field due to the surface charge on a hard layer, "A" magnetized parallel (a), or perpendicular (b) to the layer plane.

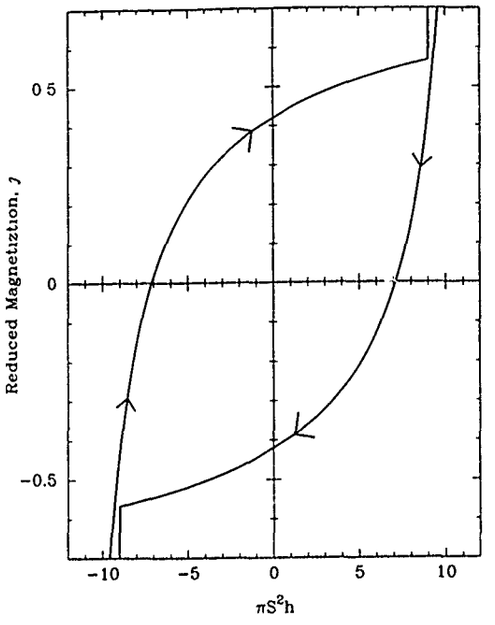

FIG. 2. An inverted hysteresis loop computed from Eqs. (1) and (4), with $\pi S^2 h_D = 12.5$.

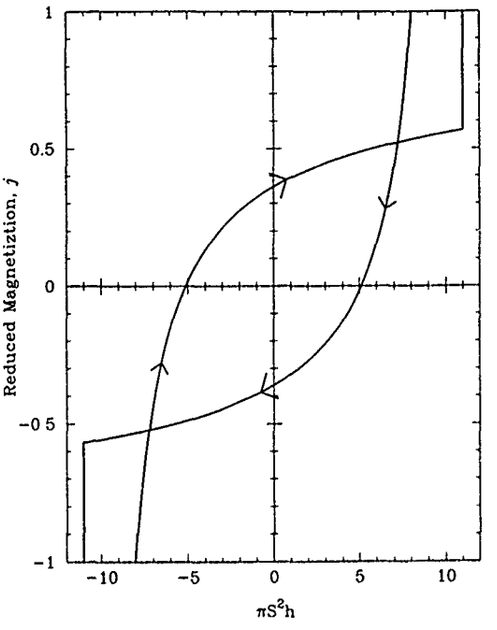

FIG. 3. As in Fig. 2, only with $\pi S^2 h_D = 10.5$. Note that the scales are different.

magnetization into the field direction. Effectively, boundary conditions no longer require the surface magnetization to be always parallel to $+z$. At a large negative field it becomes parallel to $-z$.

(2) A demagnetization is added by replacing Eq. (3) by

$$-\pi S^2(h-h_D)=[K(k)]^2. \tag{4}$$

Of course, these assumptions are oversimplified, because the CoO is not magnetized abruptly, and the demagnetization is not a *constant*, h_D. However, this simple model contains all the physics of the assumed mechanism, and it can produce the experimental curves. A typical hysteresis curve, computed from Eqs. (1) and (4) and plotted in Fig. 2, contains all the features of, and is qualitatively very similar to, the observed[1,2] inverted hysteresis loops.

The plot in Fig. 2 is sensitive to the value used for h_D. For a smaller value the increasing and decreasing part of the hysteresis curve cross, approaching the shape of the curves computed[2] with no demagnetization. An example is plotted in Fig. 3. This result is not inconsistent with the experimental observation[1,2] that the loops are not always inverted. It must mean that the geometrical details of the demagnetization are important.

It should be emphasized that the curve in Fig. 2 is *not* a true minor loop. If the decreasing-field part in Fig. 2 is stopped and reversed at, say, $\pi S^2 h = -7$, the magnetization will climb back on the *same* branch, and not on the increasing part. Changing between the two branches occurs only in a highly positive or highly negative field, where energy has to be spent on reversing the *hard* component. Presumably, the same is also true for the observed inverted loops, although this point is not specified in the published[1,2] accounts. Otherwise, the negative resistance of the minor loop could be used to create a perpetual motion machine, thus violating the second law of thermodynamics. Actually, the energy gain in small fields is more than balanced by the energy loss in higher fields, as is the case for an electronic circuit with a negative resistance in *part* of the V-I cycle.

III. ONE-DIMENSIONAL THEORY

The crude approximations of Sec. II do not allow for a magnetization distribution in the hard magnetic component, take the demagnetizing field as a constant, and do not take into account the demagnetizing of the hard by the soft component. These approximations can be much improved by a slight modification of the theory which was used[4] for bilayers of NiFe-TbCo, but which is *qualitatively* the same for any other pair of materials. It should be particularly noted that this theory contains as particular cases all the other one-dimensional models which were developed separately, e.g., when each film is taken as a "single domain," without[5] or with[6] a transition wall between them.

This theory[4] considers a soft layer whose magnetization is at an angle $\theta_1(z)$ to the axis of induced anisotropy, taken as the x axis, in the region $-t_1 \leqslant z \leqslant 0$; and a hard layer whose magnetization is at an angle $\theta_2(z)$ to x, in the region $0 \leqslant z \leqslant t_2$. For the soft and the hard films, the saturation magnetization is M_j, the uniaxial anisotropy constant is K_j, and the exchange constant is A_j, with $j=1, 2$, respectively. It is only assumed here that the soft film interacts with a field $H_A - H_{D1}$, and the hard film with $H_A - H_{D2}$, instead of just with the applied field, H_A. Here H_{D1} should *eventually* be taken as proportional to the average of $\cos\theta_2$, and H_{D2} as proportional to the average of $\cos\theta_1$, which should be a reasonably good approximation to many real physical situations. This part will be published elsewhere. The following notations are used for short:

$$h_1=(H_A-H_{D1})M_1/K_1, \quad h_2=(H_A-H_{D2})M_2/K_2,$$
$$q^2=K_b^2\sin^2(2\theta_b)/(4A_2K_2), \quad \theta_b=\theta_2(t_2), \tag{5}$$
$$\theta_0=\theta_1(-t_1), \quad Q=\sqrt{q^2+(h_2/2+\cos\theta_b)^2},$$

where K_b is[4] the surface anisotropy.

Smith and Cain[4] solved numerically the two *second-order* differential equations which minimize the energy. However, it is known[7,8] and has been pointed out[9] again, that *all* the equations of one-dimensional micromagnetics can be integrated at least once, if not twice. After the first integration, these equations become

$$(A_1/K_1)(d\theta_1/dz)^2=h_1[\cos(\theta_0-\theta_H)-\cos(\theta_1-\theta_H)] +\sin^2\theta_1-\sin^2\theta_0, \tag{6a}$$

$$(A_2/K_2)(d\theta_2/dz)^2=h_2[\cos(\theta_b-\theta_H)-\cos(\theta_2-\theta_H)] +q^2+\sin^2\theta_2-\sin^2\theta_b. \tag{6b}$$

Here θ_H is the angle between the applied field and the x axis. It can be checked that Eqs. (6) are indeed first integrals of the second-order equations[4] *and* that they fulfill two of the boundary conditions, which require the z derivatives of θ_1 and of θ_2 to vanish on $z=-t_1$ and $z=t_2$, respectively. It should be noted, though, that θ_0 and θ_b are known at this stage only as the boundary values of θ_1 and θ_2. They still need to be evaluated.

One of the remaining boundary conditions is that the derivative is continuous,

$$d\theta_1/dz=d\theta_2/dz, \quad \text{on } z=0. \tag{7a}$$

The other one was taken[4] as a certain *discontinuity* of the angle at $z=0$, thus introducing unnecessarily another, *unknown* parameter, K_t. It is better to take the limit $K_t\to\infty$, because the exchange is the largest force over short distances. Other micromagnetics studies do not allow a discontinuity because the exchange is so strong, and having an exchange coupling between two *different* materials cannot change this argument. In the studies of nucleation at crystalline imperfections, with an abrupt[10] or a gradual[11] or a periodic[12] change in the anisotropy, and in the study[13] of domain wall pinning, or wall motion[14] in a material with a variable exchange, the angle was assumed to be continuous. There is no reason to assume anything else here, and the second boundary condition is that the angle is also continuous,

$$\theta_t=\theta_1(0)=\theta_2(0). \tag{7b}$$

Analytic integration of these equations is possible in many cases, but there are different types of functions depending on the values of the physical parameters involved. The following solution is only an example, for the particular case of an in-plane field, $\theta_H=0$

$$1-\cos\theta_1=\frac{1-\cos\theta_0}{1-\frac{k_1^2}{2}(1+\cos\theta_0)\mathrm{sn}^2\left(\frac{z+t_1}{t_1}u_1,k_1\right)}, \tag{8a}$$

$$1-\cos\theta_2=\frac{1-Q+h_2/2}{1-\frac{k_2^2}{2}\left(1+Q-\frac{h_2}{2}\right)\mathrm{sn}^2(U_2,k_2)}, \tag{8b}$$

$$k_1^2=\frac{2(h_1+2\cos\theta_0)}{(1+\cos\theta_0)(1+h_1+\cos\theta_0)}, \tag{8c}$$

$$k_2^2=\frac{4Q}{(1+Q)^2-(h_2/2)^2}, \tag{8d}$$

$$u_1=\frac{t_1}{2}\sqrt{\frac{K_1}{A_1}}\sqrt{(1+\cos\theta_0)(1+h_1+\cos\theta_0)}, \tag{8e}$$

$$U_2=u_0+\frac{z-t_2}{t_2}u_2, \quad u_2=\frac{t_2}{k_2}\sqrt{\frac{K_2}{A_2}}Q, \tag{8f}$$

$$\mathrm{sn}^2(u_0,k_2)=\frac{q^2}{2Q}\left(\frac{1}{Q+\cos\theta_b+h_2/2}+\frac{1}{1-\cos\theta_b}\right), \tag{8g}$$

where sn is the Jacobian elliptic function, and where the integration constants have already been chosen so that $\theta_1=\theta_0$ on $z=-t_1$, and $\theta_2=\theta_b$ on $z=t_2$. It can be checked by differentiation that Eqs. (8) solve the differential Eqs. (6). Therefore Eqs. (8) are a legitimate solution, provided the parameters are such that

$$0<k_1^2<1 \quad \text{and} \quad 0<k_2^2<1. \tag{9}$$

If either k_1 or k_2 is not in this region, standard transformations to other elliptic functions may be used.

The problem has thus been reduced to finding θ_0 and θ_b that will fulfill the boundary conditions of Eqs. (7).

Once this problem is solved, the average magnetization in each region,

$$\langle\cos\theta_1\rangle=\frac{1}{t_1}\int_{-t_1}^{0}\cos\theta_1\,dz, \tag{10a}$$

$$\langle\cos\theta_2\rangle=\frac{1}{t_2}\int_{0}^{t2}\cos\theta_2\,dz, \tag{10b}$$

is a standard elliptic integral of the third kind. The reduced total magnetization is then

$$j=\frac{M_1t_1\langle\cos\theta_1\rangle+M_2t_2\langle\cos\theta_2\rangle}{M_1t_1+M_2t_2}. \tag{11}$$

Ruderman–Kittel–Kasuya–Yosida polarizations in inhomogeneous media

W. Baltensperger and J. S. Helman
Centro Brasileiro de Pesquisas Físicas (CBPF), Rua Dr. Xavier Sigaud 150, Rio de Janeiro, RJ 22290, Brazil

An analytical treatment of the Ruderman–Kittel–Kasuya–Yosida polarization in inhomogeneous media is possible for some simple models. This is exemplified with the half-spaces and slabs in one and three dimensions, and with an especially chosen potential barrier in one dimension.

I. INTRODUCTION

Experiments with films and with layered structures require information on the Ruderman–Kittel–Kasuya–Yosida (RKKY) polarization in inhomogeneous situations. This work deals with especially simple situations for which a calculation can be made analytically. The aim is to get familiar with effects that appear in idealized situations rather than to study a model that incorporates many features of actual experimental conditions.

As in the classical papers on RKKY polarization[1] we shall assume the electron gas to be ideal and fully degenerate. At a position **a** the electron spins are subject to a point field leading to a perturbing Hamiltonian

$$H' = -\gamma\delta^3(\mathbf{r}-\mathbf{a})\,\frac{\sigma_z}{2}. \tag{1}$$

The coupling constant γ has the dimension energy volume, **r** is the electron position, and σ_z the Pauli spin matrix for the z direction. In the homogeneous case plain waves $\phi_{k,s} = 1/\sqrt{\pi}e^{i\mathbf{k}\cdot\mathbf{r}}|s\rangle$, with $s=\pm\frac{1}{2}$ the spin quantum number, and which belong to the energy $\epsilon(\mathbf{k})=\hbar^2k^2/2m$, form a complete set of unperturbed one particle states. It can be shown by an extension of Yosida's argument[2] to inhomogeneous situations, Eq. (33), that the first-order perturbed wave functions

$$\psi_{k,s} = \phi_{k,s} + \int d^3\mathbf{k}'\,\frac{\langle\phi_{k',s'}|H'|\phi_{k,s}\rangle}{\epsilon(\mathbf{k}')-\epsilon(\mathbf{k})}\,\phi_{k',s}, \tag{2}$$

lead to the correct spin polarization which has z direction:

$$P(\mathbf{x}) = \frac{1}{(2\pi)^3}\int_{k<k_F} d^3\mathbf{k}\,\psi^*_{k,s}(\mathbf{x})\,\frac{\sigma_z}{2}\,\psi_{k,s}(\mathbf{x}). \tag{3}$$

k_F is the Fermi wave vector

II. THE SEMISPACE

Consider an ideal electron gas confined to the half-space with coordinate $x>0$. This is obviously not a realistic model for a surface of a true metal. However, it has the virtue that again a simple set of one particle functions can be written down. In the one-dimensional case they can be taken to be $1/\sqrt{2}\sin(kx)|s\rangle$. The electron density and therefore the polarization vanishes at the surface. Mathematically the whole change is a sine function in place of an exponential. In the unlimited one-dimensional space the spin polarization is[3,4]

$$R_1(|x-a|) = \frac{\gamma}{4\pi}\,\frac{2m}{\hbar^2}\left(\frac{\pi}{2} - \mathrm{Si}(2k_F|x-a|)\right). \tag{4}$$

For the half-line the calculation[5] gives

$$P_{1h}(x) = R_1(|x-a|) + R_1(x+a) - 2R_1[|x-a|/2 + (x+a)/2]. \tag{5}$$

The first term is the polarization in a homogeneous medium due to a point field at position a, and the second is the same expression centered around the mirror point $-a$. At the surface, $x=0$, the two terms have the same value. In this sense the second term is not a reflected wave. It is the third term, which depends on the average distance to the source and to its mirror point, which compensates the first two terms at the surface. P_{1h} is shown in Fig. 1.

When the half-space has more than one dimension, a complete set of one particle wave functions which vanish at the boundary $x=0$ is

$$\phi_{k,K,s}(x,\mathbf{R}) = \sqrt{2}\,\sin(kx)e^{i\mathbf{K}\cdot\mathbf{R}}|s\rangle, \tag{6}$$

where $k>0$, and **R** and **K** are orthogonal to the x direction. In two dimensions the authors were unable to perform the integrations analytically. For a three-dimensional half-space the polarization P_h can again be expressed[5] in terms of the usual RKKY function

$$R(x) = \frac{\gamma k_F^4}{4\pi^3}\,\frac{2m}{\hbar^2}\,\frac{\sin(x)-x\,\cos(x)}{x^4} \tag{7}$$

as

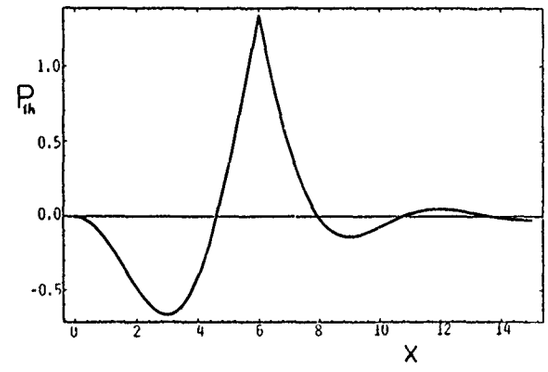

FIG. 1. The spin polarization $P_{1h}(x)$ in a half-line for a point field at $a=6$. Distances are in units of $1/(2k_F)$ and P_{1h} is in units of $\gamma 2m/(4\pi\hbar^2)$

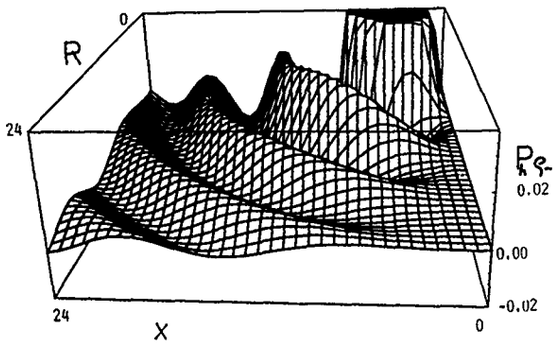

FIG. 2. Polarization in half-space due to a point field at $a=4$. $P_h(x,R)\rho_-$ is shown, where the factor ρ_-, the distance to the point source, suppresses the divergence of P_h at the source and emphasizes the oscillations. Distances are in units of $1/(2k_F)$ and P_h is in units of $\gamma k_F^4 2m/(4\pi^3\hbar^2)$.

$$P_h=R(2k_F\rho_-)+R(2k_F\rho_+)-\frac{(\rho_-+\rho_+)^2}{(2\rho_-\rho_+)}R[k_F(\rho_-+\rho_+)]. \tag{8}$$

Here

$$\rho_\mp=\sqrt{(x\mp a)^2+R^2}, \tag{9}$$

so that ρ_- is the distance to the source and ρ_+ to its mirror point. The first two terms are spherical waves, while the third term depends on $\rho_++\rho_-$ and compensates the first two at the surface. See Fig. 2.

III. THE SLAB

In the one-dimensional case, i.e., for the finite line of length L, a closed expression for the polarization $P_{1f}(x)$ has been derived.[5] The plot in Fig. 3 assumes an even number of electrons N, so that the highest occupied level is designated by $n_F=N/2$. In three dimensions, for the slab of width L, the polarization $P_f(x,R)$ can be written as a rapidly converging series.[5] Here, x, with $0<x<L$, and R are coordinates of a circular cylinder with the source at $x=a$, $R=0$. Figure 4

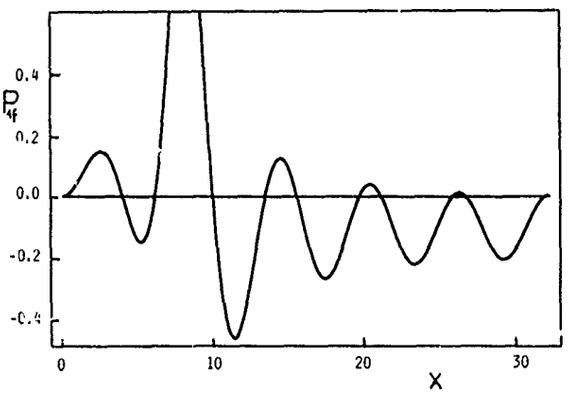

FIG. 3. Polarization in a finite line of length $L=32$ due to a point field at $a=8$. $n_F=5$. Units are as in Fig. 1. The precise position a determines whether the positive polarization near a is compensated by a negative one mostly to the right or to the left of a.

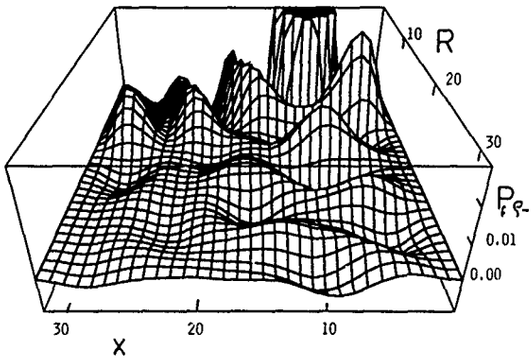

FIG. 4. The spin polarization $P_f(x,R)\rho_-$ in a slab of width $L=32$. $a=12$. Units are as in Fig. 2.

shows $P_f\rho_-$, where ρ_- is the distance from the source. $n_F=\mathrm{Int}(\pi k_F/L)=5$ designates the band at the Fermi level.

IV. POLARIZATION ACROSS A POTENTIAL WELL

A potential also creates an inhomogeneity in an electron gas. A square well leads to wave functions with somewhat complicated coefficients which inhibit a further analytical treatment. A numerical calculation has been performed by Jones and Hanna.[6] Here we discuss a one-dimensional model with a particular localized potential which lends itself to analytic treatment.

The electrons are subject to a localized potential of width λ

$$V(x)=-V_0\ \mathrm{sech}^2(\lambda x) \tag{10}$$

$$V_0=2\lambda^2\hbar^2/(2m), \tag{11}$$

where m is the mass of an electron. With Eq. (11) the potential has the remarkable property of being reflectionless.[7] Note that Eqs. (10) and (11) imply that the depth and width of the potential cannot be varied independently. This potential has been chosen for the simplicity of its wave functions and spectrum. This consists of a continuous part

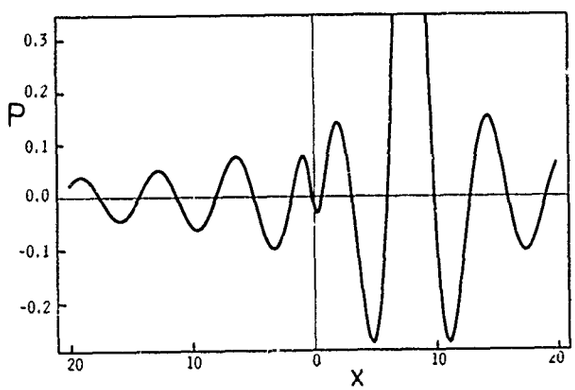

FIG 5. Spin polarization due to a point source at $a=3$ in the presence of a potential, Eq. (23) with $\lambda=1$, near $x=0$. Units are as in Fig 1.

$$\phi_{k,s}(x)=\frac{-ik+\lambda\tanh(\lambda x)}{\sqrt{k^2+\lambda^2}}e^{ikx}|s\rangle,\quad E_k=\frac{\hbar^2k^2}{2m},\tag{12}$$

and one bound state

$$\phi_{b,s}(x)=\sqrt{\frac{\lambda}{2}}\,\mathrm{sech}(\lambda x)|s\rangle,\quad E_b=-\frac{\hbar^2\lambda^2}{2m}.\tag{13}$$

With

$$z=|x-a|,\tag{14}$$

$$T=\tanh(\lambda x)\tanh(\lambda a),\tag{15}$$

$$S=|\tanh(\lambda x)-\tanh(\lambda a)|,\tag{16}$$

$$C_k=\frac{(k^2+\lambda^2T)\cos(kz)-k\lambda S\,\sin(kz)}{k^2+\lambda^2},\tag{17}$$

the polarization becomes

$$P(x,a)=-\frac{2m}{\hbar^2}\frac{\gamma}{4\pi}\left\{-\frac{\pi}{2}T^2+\int_0^{k_F}\frac{dk}{k}\frac{1}{(k^2+\lambda^2)^2}\{[(k^2+\lambda^2T)^2-(k\lambda S)^2]\sin(2kz)+2\lambda Sk(k^2+\lambda^2T)\right.$$
$$\times\cos(2kz)\}+2\lambda[e^{-\lambda z}(T-1-S)+\mathrm{sech}(\lambda x)\mathrm{sech}(\lambda a)]\int_0^{k_F}dk\,\frac{C_k}{(k^2+\lambda^2)}-\frac{\pi}{2}\,\mathrm{sech}(\lambda x)$$
$$\left.\times\mathrm{sech}(\lambda a)e^{-\lambda z}[T+1+\lambda z(T-1-S)]\right\}.\tag{18}$$

This still contains an integration to be performed numerically (Fig. 5).

As a limiting case let both x and a be on the same side of the potential and far away from it, i.e.,

$$x,a\gg\lambda,\quad\text{or}\quad -x,-a\gg\lambda.\tag{19}$$

In this case $T=1$ and $S=0$. Thus $P(\mathbf{x},\mathbf{a})\approx R_1(|\mathbf{x}-\mathbf{a}|)$ of Eq. (4). Note that the terms that were neglected were exponentially small. This result conforms with the reflection free property of the potential. In general $P(a,a)=\gamma 2m/(4\pi\hbar^2)$ independent of a and λ.

V. INTEGRATED POLARIZATION

The validity of the procedure used by Ruderman and Kittel to derive the polarization induced by a point field was demonstrated by Yosida. This can be extended to situations in which the electron gas is subject to boundary conditions and spin independent potentials. Let $\phi_{\kappa,\nu}(\mathbf{x})$, $\epsilon(\kappa,\nu)$ represent the orbital wave functions and energies of the continuous part of the spectrum, where κ is a continuous quantum number while ν labels the bands. Then it can be shown that the polarization satisfies

$$\int P(\mathbf{x},\mathbf{a})d^3x=\frac{\gamma}{(2\pi)^2}\sum_\nu\int_{S_{F,\nu}}\frac{dS_{\kappa,\nu}}{4\pi}\frac{|\phi_{\kappa,\nu}(\mathbf{a})|^2}{|\nabla_\kappa\epsilon(\kappa,\nu)|},\tag{20}$$

where the integration extends over the Fermi surfaces $S_{F,\nu}$ of all bands that are partially filled. The right-hand side can be interpreted as counting the spin flips at the Fermi energy due to the point field. However the formula is derived using perturbed wave functions and the unperturbed occupation of states. The bound states contribute only indirectly, through the orthogonality to the continuous states. Apart from justifying our method of calculation, Eq. (20) provides a shortcut to obtain the integrated polarization.

Spin reversal in Co/Au(111)/Co trilayers

V. Grolier, J. Ferré, M. Galtier,[a] and M. Mulloy[a]
Laboratoire de Physique des Solides, Bât. 510, Université Paris-Sud, 91405 Orsay Cedex, France

In Co/Au(111)/Co trilayers exhibiting oscillatory interlayer coupling, we show how the nature and the strength of this interaction modify the magnetization reversal. In the case of antiferromagnetic (AF) coupling the magnetic domain patterns observed by Faraday microscopy differ drastically according to the amplitude of the coupling. This effect can be understood on the basis of the fluctuations of the effective field acting on a layer produced by the roughness of the Au interlayer. Among the ferromagnetically (F) coupled layers slighter differences are visible that can be accounted by changes of the anisotropy energy.

INTRODUCTION

Widely observed in systems with planar anisotropy, the oscillatory interlayer coupling has been detected in few systems with perpendicular anisotropy.[1,2] Among them Co/Au(111)/Co is particularly attractive in view to study the magnetization reversal and the corresponding domain patterns, because much of the work has been devoted to simple Au/Co/Au sandwiches.[3,4] The purpose of this article is to show how the spin reversal near the coercive field(s) is affected by the interlayer coupling and its oscillatory nature and to understand this behavior in light of what is already known about Au/Co/Au monolayers.

SAMPLES AND EXPERIMENTAL TECHNIQUES

The samples are Co/Au(111)/Co trilayers grown by thermal evaporation in ultrahigh vacuum on a polycrystalline fcc Au(111) buffer. Details about the growth conditions and the structural properties of the samples are reported elsewhere.[1]

The Au interlayer has a stepped-wedge shape, with eight different thicknesses, from 2 to 9 atomic layers (AL). The two Co films have the same thickness—0.8 nm—and comparable roughness (1 AL) in this range of Au interlayer thickness, as was shown by AFM and RHEED experiments.[5] Therefore, for the thinnest samples ($t_{Co} \leqslant 3$ AL), we can expect that in the absence of coupling the top and the bottom layers have almost the same intrinsic coercive field and exhibit similar domain patterns during the reversal of magnetization.

All the samples have perpendicular anisotropy and their magnetization was deduced from sensitive Faraday ellipticity measurements. At a more microscopic scale a Faraday microscope with an objective of high numerical aperture (0.85) was used to observe domain patterns.

RESULTS

The hysteresis loops (Fig. 1) measured in perpendicular field confirm the oscillatory nature of the interlayer coupling: for $t_{Au}=5$ AL and 9 AL we observe two successive jumps of magnetization at different fields, thus revealing AF coupling. For the other interlayer thicknesses, only one steep reversal is visible, occurring at a smaller coercive field for the thinnest interlayers ($t_{Au}=2$ AL and 3 AL).

In the case of AF coupling, the two coercive fields are different enough to enable the observation of the domains in each Co layer separately. For strong AF interaction, the time evolution of the domain structures after premagnetizing the sample in a large negative field are shown Fig. 2. The first layer exhibits a dendritic growth of domains starting from a few nucleation centers. The situation is completely different in the second layer: a great amount of small domains are nucleated and very limited propagation of their walls is visible afterwards.

For small AF coupling ($t_{Au}=9$ AL), if the reversals occur at different fields, the corresponding evolutions of the domain patterns (Fig. 3) are identical: a domain wall is moving across the sample with a reduced deformation of its shape by pinning centers.

Among the F coupled samples the less strongly coupled ones ($t_{Au}=4$, 6, 8 AL) form an homogeneous group with the same coercive field and identical domain patterns. The strongly F coupled films ($t_{Au}=2$, 3 AL) behave differently, which appear clearly on magnetic after-effect curves. For these samples, one has to notice that beside the regular RKKY coupling a direct exchange interaction exists. Figure 4 illustrates the influence of the strength of the F coupling on relaxation curves obtained for $t_{Au}=2$ and 4 AL. Both the bias fields and the shape of the relaxation are different: for $t_{Au}=4$ AL we get a typical reversal dominated by domain wall propagation, whereas for $t_{Au}=2$ AL, the nucleation process plays a more important role and the needed applied fields are smaller.

INTERPRETATION

Bruno and Chappert,[4] first have pointed out in this system the importance of the inhomogeneities in the determination of the coercivity via domain wall movement. In the case of coupled films, the effective field acting on each layer is

$$H_{eff}=H_{appl}+H_{int},$$

where H_{appl} and H_{int} are the applied and interaction fields, with $H_{int}>0$ for AF coupling. Therefore, to the inhomogeneities due to the structural roughness of each Co layer the ones produced by the fluctuations of H_{eff} due to the roughness of the interlayer are added.

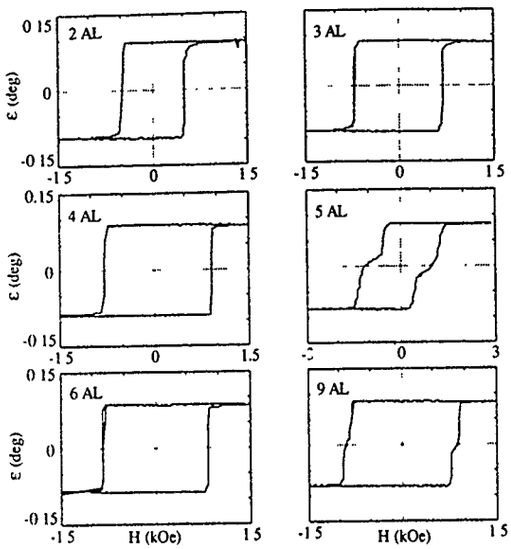

FIG. 1. Hysteresis loops measured by magneto-optical Faraday ellipticity for different values of the Au interlayer thickness.

When t_{Au}=5 AL, the coupling is AF but its amplitude and its sign are very sensitive to the Au layer thickness.[1] In that case, taking into account a realistic roughness of the interlayer of 1 AL, islands of F coupled zones exist in a majority of AF coupled regions. It must be noted that this picture of islands is reasonable when the mean interlayer thickness is smaller than the so-called cutoff thickness equal to 5 AL in this system.[6] For the first Co layer, nucleation occurs where the effective field is the highest (AF zones) and the F islands act as obstacles to be avoided by the moving wall, which explains the dendritic shape of the walls. In the second Co layer, nucleation occurs in F zones and very rapidly, the domain wall reaches an AF region which stops its motion.

For t_{Au}=9 AL, we are beyond the cutoff thickness and the fluctuations of the coupling are much smaller than near the first AF peak, namely 0.05 erg cm^{-2} for a change of the interlayer thickness of 1 AL. Besides, the variation of the anisotropy energy due to the roughness of each Co film is 0.1 erg cm^{-2} when t_{Co}=0.8 nm. Therefore, in this case, the AF

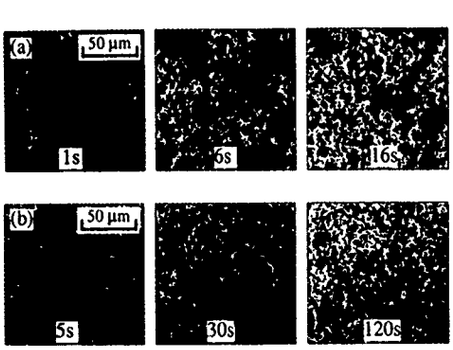

FIG. 2. Co(0.8 nm)/Au(5 AL)/Co(0.8 nm): time evolution of the magnetic domain structure in the first Co layer (a) at H=336 Oe and in the second one (b) at H=1008 Oe.

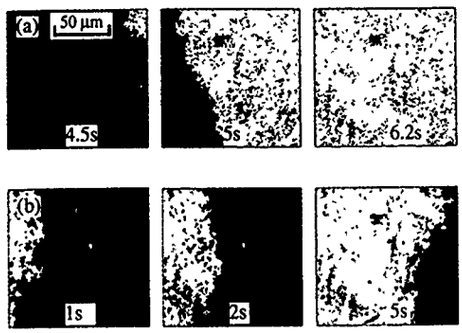

FIG. 3. Co(0.8 nm)/Au(9 AL)/Co(0.8 nm): time evolution of the magnetic domain structure in the first Co layer (a) at H=624 Oe and in the second one (b) at H=768 Oe.

coupling just shifts the magnetization reversals with respect to one another, but does not alter their mechanisms as compared to a single Au/Co/Au sandwich with t_{Co}=0.8 nm.

When the coupling is F another effect accounts for the differences observed between weakly and strongly coupled Co layers. The magnetic anisotropy of the above-mentioned samples (t_{Au}=2 and 4 AL) was compared to the one of a Au/Co/Au sandwich (t_{Co}=0.8 nm). For this purpose, the magnetic field is applied to 25° with respect to the sample plane and the variation of the perpendicular component of the magnetization is recorded as a function of the field amplitude.[7] The results are shown Fig. 5.

Whereas the sample with t_{Au}=4 AL is similar to the single Co film from the point of view of magnetic anisotropy, the strongly coupled one (t_{Au}=2 AL) is softer and is comparable to a single 1.2-nm thick Co layer.

Therefore, the differences observed in Fig. 4 can be understood on the basis of the effective thickness deduced from the anisotropy measurements. They correspond to the trends

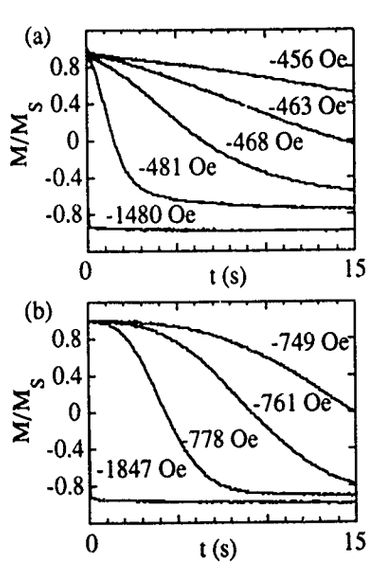

FIG. 4. Magnetic after effect for t_{Au}=2 AL (a) and t_{Au}=4 AL (b) for different values of the applied field.

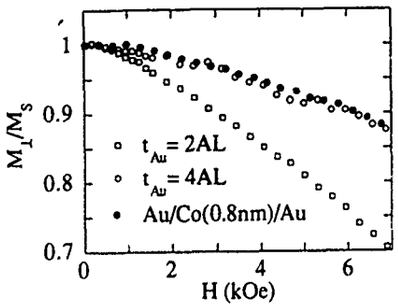

FIG. 5. Variation of the normal component of the magnetization under application of a magnetic field at 25° with respect to the film plane for two trilayers with t_{Au}=2 AL and t_{Au}=4 AL and for a 0.8-nm-thick Co monolayer.

observed for Au/Co/Au sandwiches: decrease of the coercive field, importance of the nucleation process when the Co thickness is increased.[8]

CONCLUSIONS

As for Co monolayers, the fluctuations play an important role in the dynamics of the magnetization reversal but contrary to the former case these fluctuations are not due to the own roughness of the Co films but results from the one of the Au interlayer. This effect is enhanced by the sensitivity of the coupling to the Au thickness, especially near the first AF peak. At lower thicknesses (strong F coupling), the differences originate from the decrease of the magnetic anisotropy for thin Au interlayers.

Effect of coupling on magnetic properties of uniaxial anisotropy NiFeCo/TaN/NiFeCo sandwich thin films

T. Yeh, L. Berg, P. Witcraft, J. Falenschek, and J. Yue
Honeywell, Solid State Electronics Center, Plymouth, Minnesota 55441

The coercivity of the coupled NiFeCo thin films is a function of nickel-iron-cobalt (NiFeCo) film thickness and tantalum nitride (TaN) intermediate layer thickness. This can be attributed to the variation of energy and magnetization gradients of a domain wall. The magnetization gradient can be affected by a thickness-induced coupling effect associated with altering the exchange and magnetostatic interactions between the two NiFeCo films. Decreasing the exchange coupling and increasing the magnetostatic coupling between the coupled NiFeCo films tends to decrease the energy and magnetization gradients of domain walls and results in decreased coercivity.

INTRODUCTION

The success of utilizing coupled magnetic films as magnetic sensors or memories largely depends upon a better understanding and control of the magnetic coupling between the coupled magnetic films. One of the most striking effects of sandwich magnetic films, as compared to that of a single film, is the reduction of coercivity, which is attributed to reduced domain wall energy.[1–4] Theoretical calculation showed that the domain wall energy of coupled films can be significantly changed through the exchange and magnetostatic coupling of the coupled films by varying the thickness of magnetic and nonmagnetic films.[2,5,6] In this article, the manner in which the magnetic properties of coupled NiFeCo films are affected by pure tantulum (Ta) and reactive-sputter TaN films is examined, and the magnetic properties of sandwich NiFeCo/TaN/NiFeCo films as a function of TaN and NiFeCo film thicknesses are investigated. Also, the correlation between the coercivity of the coupled films and the domain wall is discussed.

EXPERIMENT

Because of the nature of short-range interaction, the exchange coupling of coupled films may be very sensitive to the thickness of the nonmagnetic interlayer and the interlayer material. The experiments for this article were performed as follow. First, the effect of Ta and TaN intermediate layers on magnetic properties of 150-Å-thick coupled NiFeCo films was investigated. Second, how the nonmagnetic intermediate layer thickness affects the magnetic properties of the coupled films was studied. In this portion of the study, the 150-Å-thick NiFeCo film was used with the intermediate TaN film thickness varying from 0 to 105 Å. Third, in an attempt to study the magnetostatic coupling effect on the magnetic properties of the sandwich films, the NiFeCo films were varied from 150 to 600 Å with the intermediate TaN film held constant at 50 Å.

Samples of NiFeCo/TaN/NiFeCo sandwich films were sputter deposited on a 4-in. silicon wafer coated with a thin sputtered silicon nitride film. rf sputtering was used to deposit the NiFeCo films while the TaN was deposited by a dc reactive-sputter process with an Ar and N_2 mixture sputtering gas and a pure Ta target producing the NiFeCo/TaN/NiFeCo sandwich. The deposition rates of the films were carefully characterized while the thickness of the films was controlled by varying the sputtering time.

Subsequent to the deposition, the film properties were characterized by a B-H looper using a maximum 100-Oe applied field. The sheet resistance and B's of the films were used to monitor the thickness of the NiFeCo films. The magnetic properties of the films, such as skew, dispersion α_{90}, anisotropy field H_K, and coercivity $H_{c//}$, were determined by the B-H looper measurements. Atomic force microscopy (AFM) was used to characterize the surface topography of the sandwich films.

The magnetic properties of the sample films are summarized in Tables I, II, and III. The skew and dispersion α_{90} data demonstrate that all the sample films exhibit in-plane magnetic unaxial anisotropy with easy and hard axes perpendicular to each other. A typical easy and hard axis hysteresis loop of the sandwich film is shown in Fig. 1. The anisotropy field H_K of the film was measured to be approximately 20 Oe, showing results of the easy and hard axes hysteresis loops to be consistent with the skew and dispersion α_{90} measurements.

RESULTS AND DISCUSSION

Before reporting and discussing the experimental results, we will first derive the relationship between coercivity and the domain wall energy of the coupled films. Because of the coupling effect in the configuration of two ferromagnetic films separated by a nonmagnetic film, the domain wall structure differs markedly from those observed in single ferromagnetic films. One of the most striking properties of coupled magnetic films is the modification of domain wall reversal properties by comparison with those of single films. The coercivity is a quantitative measure of the magnetic field required to reverse the magnetization direction in the film. Local energy gradients constitute a generalized force tending to hinder the magnetization reversal process of a ferromagnetic film.[7] However, for a magnetic uniaxial anisotropy film, the local energy gradients of domain walls are the dominant hindrance of the magnetization reversal process. If we call the domain wall energy γ, the coercivity is related to the derivative of this energy with respect to position $d\gamma/dx$, the energy gradient.[8]

 0021-8979/94/76(10)/6986/3/$6.00 © 1994 American Institute of Physics

TABLE I. Magnetic properties of the coupled NiFeCo films with different nonmagnetic intermediate layers.

NiFeCo thickness (Å)	Interlayer thickness (Å)	B_s (nW)	Skew (degree)	Dispersion (degree)	H_K (Oe)	H_{cl} (Oe)
150	50 (TaN)	2.41	0.52	0.7	20.0	0.45
150	50 (pure Ta)	2.34	−0.23	0.8	20.0	1.38

The total energy of the wall configuration is given by the sum of magnetostatic, anisotropy, and exchange terms, assuming that the domain wall is Néel and quasi-Néel type and the wall is thick compared to the total thickness of the sandwich film.[2,5,9] Therefore, the coercivity of the coupled films can be derived to be:[2]

$$H_{c//}=\left.\frac{d\gamma}{dx}\right|_{\max}=2\pi D\left(\frac{1}{2}b+\frac{1}{3}D\right)\left(\frac{dM_x}{dx}\right)^2+K\cos^2\varphi+A\left(\frac{d\varphi}{dx}\right)^2, \quad (1)$$

where D and d are thicknesses of the magnetic films and the nonmagnetic interlayer, respectively, K is the effective anisotropy constant, and A is the exchange constant. One may note that the coercivity $H_{c//}$ is a function of dM_x/dx and $d\varphi/dx$, the magnetization gradients, with lower magnetization gradient resulting in lower coercivity. Also, a domain wall with lower magnetization gradient implies a wider domain wall width. In other words, the domain wall width would be wider for the coupled film with lower coercivity due to lower magnetization gradient. The width of the domain wall appears to be inverse proportional to the square root of the coercivity $H_{c//}$.

Now, we move to a discussion of the effect of different intermediate layers on magnetic properties of the coupled NiFeCo films. The coercivity of the coupled NiFeCo films separated by a 50-Å thick Ta film is measured to be 1.38 Oe, while the coercivity is reduced to 0.45 Oe when the coupled films are separated by a 50-Å thick reactive-sputter TaN film. No effect from the anisotropy field H_K on the coercivity would be expected because of the same H_K were obtained in the two sample films. The coercivity reduction of the coupled NiFeCo films with a TaN intermediate layer could be attributed to the TaN film inducing a lower energy and magnetization gradient of the domain wall by altering the exchange and magnetostatic interactions between the magnetic films.

TABLE II. Magnetic properties of the coupled NiFeCo films as a fuction of TaN thickness (Fig. 3).

NiFeCo thickness (Å)	TaN thickness (Å)	B_s (nW)	Skew (degree)	Dispersion (degree)	H_K (Oe)	H_{cl} (Oe)

600	50	10.12	0.54	0.5	23.6	0.25

The coercivity reduced by the intermediate TaN film may also have an impact on the domain wall structure of the coupled film.

The magnetic properties of coupled 150-Å NiFeCo films with varying TaN film thickness are summarized in Table II. The coercivity of the film with no TaN interlayer is measured to be 2.16 Oe, but when the film is separated by a 17-Å TaN film, the coercivity decreases to 0.55 Oe. The anisotropy field H_K decreases from 22.2 Oe for the film with no TaN interlayer to 19.9 Oe for the film separated by a 17-Å TaN film. This decreasing in H_K implies that the anisotropy constant K of the film separated by a 17-Å TaN film is 10% lower, but the 10% decrease in the anisotropy constant alone cannot explain the four times reduction of the coercivity. The

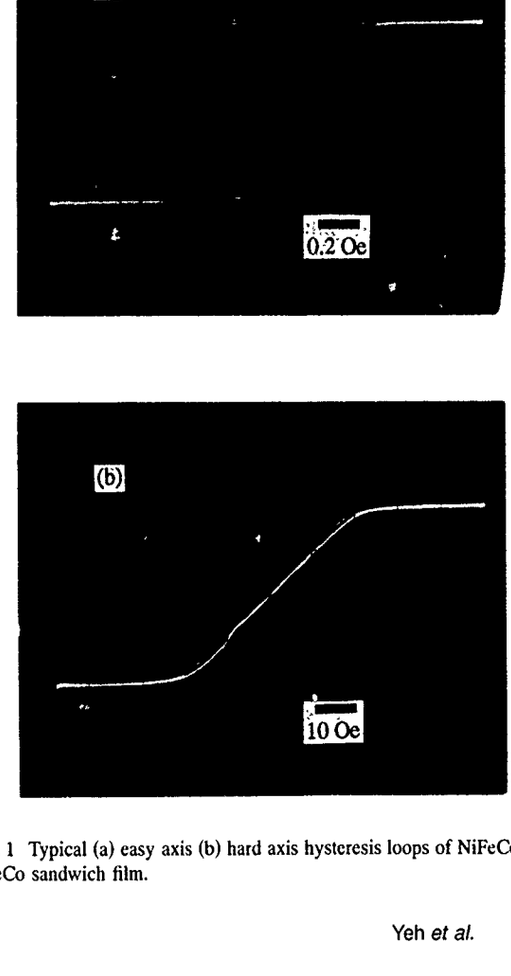

FIG. 1 Typical (a) easy axis (b) hard axis hysteresis loops of NiFeCo/TaN/NiFeCo sandwich film.

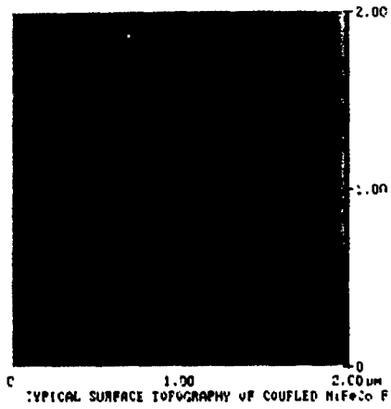

FIG. 2. The surface topography of the coupled film (rms roughness=3.4 Å).

coercivity reduction may be attributed to lowering the magnetization gradient of the domain wall induced by the 17-Å intermediate TaN film. The intermediate TaN film may induce the magnetostatic coupling and decouple the exchange interaction between the two NiFeCo films. The surface topography of the sample film shown in Fig. 2 demonstrates very smooth surface roughness. The surface roughness of the film indicates that a 17-Å thick intermediate TaN film is thick enough and continuous enough for the exchange coupling between the magnetic films to be weak or negligible, and for the magnetostatic interaction between the separated films to be appreciable which results in reducing the coercivity.

The coercivity as a function of the TaN intermediate layer thickness is shown in Fig. 3. As the TaN interlayer thickness increases, the coercivity decreases due to degradation of the exchange coupling between the magnetic films when the coercivity reaches a minimum at 50 Å. When the exchange interaction is degraded, the magnetostatic interaction between the two magnetic films comes to play a dominant role in determining the coercivity. While increasing the intermediate TaN thickness further, the magnetostatic interaction between the coupled NiFeCo films decreases and results in increasing the coercivity.

The dependence of coercivity on TaN thickness could be caused by variation of the energy and magnetization gradi-

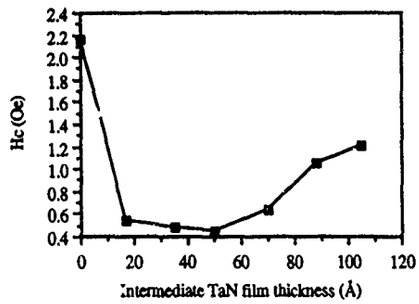

FIG. 3. The coercivity of the coupled films as a function of TaN thickness (Table II).

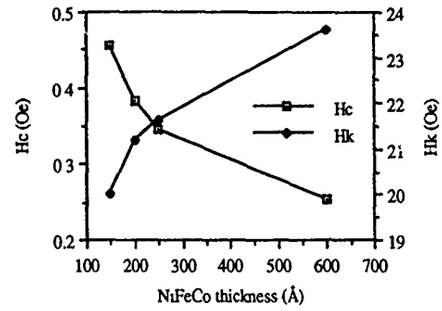

FIG. 4. The coercivity and anisotropy field of the coupled films as a function of NiFeCo thickness (Table III).

ents induced by varying the intermediate TaN thickness. Both the exchange and magnetostatic coupling between the coupled film could play a dominant role in different thickness regimes. The intermediate TaN film thickness may also have an effect on the domain wall structure.

Table III summarizes the effect of magnetostatic coupling on the magnetic properties of coupled films when varying the NiFeCo film thickness. The coercivity and anisotropy field of the coupled films as a function of NiFeCo film thickness is plotted in Fig. 4. The coercivity was found to decrease when increasing the thickness of the NiFeCo film, while the anisotropy field H_K increased when increasing the NiFeCo film thickness. This increasing of the anisotropy field can be attributed to the NiFeCo film thickness-induced magnetostatic coupling. Increasing the magnetostatic coupling between the uniaxial anisotropy coupled films tends to increase the coupling strength along the easy axis and results in lowering the energy state. For this reason, the anisotropy field increased when increasing the thickness of NiFeCo film. A higher anisotropy field H_K of the film would cause the coercivity to increase; therefore, the reduction of the coercivity is not due to increasing the anisotropy field. In this case, the coercivity can be related to the energy and magnetization gradients of the domain wall being decreased by increasing the magnetostatic coupling due to the thicker NiFeCo film.

In summary, decreasing the energy and magnetization gradients of a domain wall through altering the exchange and magnetostatic interactions between the coupled magnetic films is responsible for the reduction of the coercivity of the coupled films.

We have calculated the local magnetic moments and magnetic order for a Fe(Cr) monolayer adsorbed on a stepped Cr(Fe)(107) substrate. The electronic structure at $T=0$ K has been self-consistently determined within the unrestricted Hartree–Fock approximation of the Hubbard Hamiltonian in the framework of a real-space tight-binding method. In the Cr/Fe(107) system, two magnetic arrangements have been obtained, the more stable being the less frustrated as obtained in the case of V overlayers on vicinal substrates of Fe. An analysis of both solutions in terms of the total energy calculation and the different degree of frustration is presented. For Fe/Cr(107), a two-step periodicity is obtained. The sign of the magnetization at the Fe overlayer changes from step to step. This spin-flop transition is consistent with the two-layer period oscillation recently observed in Fe/Cr/Fe wedge structures, and with the total magnetization determined from *in situ* magnetometer measurements during growth of ultrathin Fe films on Cr(001).

Considerable attention has been devoted for 15 years to the study of a possible enhancement of the spin polarization at the surface of Fe and Cr[1–6] and, more recently, to a physically transparent explanation of the exchange coupling of adjacent Fe layers across a Cr spacer. Antiferromagnetic exchange coupling of adjacent Fe layer magnetizations through Cr layers was found by Grünberg *et al.*[7] through light scattering and by Baibich *et al.*[8] through magnetoresistance experiments. Besides oscillations from ferromagnetic (FM) to antiferromagnetic (AFM) exchange couplings with a long period, Unguris, Celotta, and Pierce[9] and Purcell *et al.*[10] have discovered oscillations with a period of two Cr monolayers when the crystallographic quality of the Fe/Cr interface is extremely good. The coupling was measured on a sample consisting on a Fe(100) single-crystal whisker substrate, a Cr wedge deposited by molecular beam epitaxy and covered by the Fe overlayer. As discussed in those papers,[9,10] the sign of the polarization of the Fe overlayer changes from step to step.

There is agreement between most of the theoretical calculations concerning the Fe/Cr systems, whereas the experimental results indicate the possibility of complex magnetic behaviors in some cases. In a recent work, Turtur and Bayreuther[11] have used an *in situ* alternating gradient magnetometer (AGM) to continuously monitor the magnetic moment in ultrathin Cr films on Fe(100) during growth in ultrahigh vacuum with submonolayer sensitivity. They have reported an evident deviation from layered-AF order in the first two–three Cr monolayers, a very strong moment enhancement in submonolayer Cr films, and a complex magnetic order of Cr moments close to the Fe substrate. From these results the necessity of further band and total-energy calculations for corresponding model structures in these Fe/Cr systems is obvious.

It is the aim of this communication to explore the experimental results obtained by Unguris *et al.* and Purcell *et al.* for the Fe/Cr wedge structure, and to investigate the possible magnetic arrangements one can find at Cr monolayers deposited on nonideal substrates of Fe, as a first step for understanding the complex behaviors one can expect for thicker coverages.

In the following we present and discuss the results (local magnetic moments and magnetic order) obtained for the monolayer of Cr adsorbed on the stepped (107) substrate of Fe and for the monolayer of Fe on Cr(107). For this study, we have calculated the spin-polarized electronic-charge distribution for the valence $3d$ electrons using a self-consistent tight-binding real-space model within the unrestricted Hartree–Fock approximation of the Hubbard Hamiltonian. This method has been recently applied to describe the spin polarization at the Fe/V interface[12] and at vicinal surfaces of Cr.[13] Instead of going into detail, we refer the reader to these works.

In Fig. 1 we show the two magnetic arrangements obtained for Cr/Fe(107). In both cases, a periodicity of one step is obtained, together with AF coupling between most of the Cr atoms and the Fe substrate. Moreover, the Cr atoms at the edge of the step and at the kink positions are antiferromagnetically coupled. This result, which is consistent with the tendency of Cr to present AF coupling between nearest neighbors, gives an indication of the importance of the short-range-order interactions in these materials. These two solutions differ, however, in the degree of frustration. The main qualitative difference between them arises from a change of the sign of the local magnetization at the Cr atoms located at the kink and edge of the step. In the solution (a), the Cr at the edge displays a magnetic moment of $-1.51\mu_B$, and the Cr

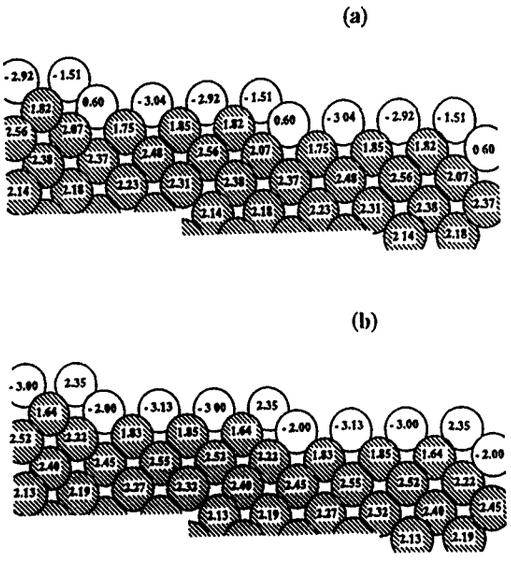

FIG. 1. Magnetic moment μ (in units of μ_B) per atom for the two solutions (a) and (b) obtained for the Cr monolayer adsorbed on the stepped (107) substrate of Fe. Open circles represent the Cr atoms whereas the filled circles represent the Fe atoms. The figure is given by projection in the (010) plane.

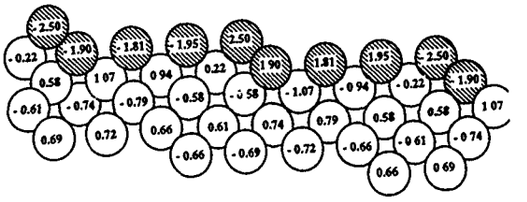

FIG. 2. Magnetic moment μ (in units of μ_B) per atom obtained for the Fe monolayer adsorbed on the stepped (107) substrate of Cr.

atom at the kink, a moment of $0.60\mu_B$, which is ferromagnetically coupled with four nearest-neighbor Fe atoms of the subsurface layer. Since Fe and Cr nearest neighbors tend to couple antiferromagnetically, strong frustration is present in the surrounding of the defect for solution (a). In contrast, in the solution (b), only the Cr atom at the edge (which displays a moment of $2.35\mu_B$) is ferromagnetically coupled with two nearest-neighbor Fe atoms of the subsurface layer. Thus, the degree of frustration is lower in solution (b) and the local magnetization around the defect results larger than in the solution (a). A total-energy calculation for the two magnetic arrangements gives a difference of 0.009 eV per atom within the cell of Fig. 1, which stabilizes the less frustrated solution (b). The same magnetic arrangement has been obtained as the more stable one in vanadium overlayers on vicinal substrates of iron.[14] A detailed inspection of the energy contribution of each atom within the system shows that most of the difference in the energy comes from the surrounding of the defect (kink and edge atoms) up to second nearest neighbors, indicating that the different degree of frustration plays an important role in the stabilization of solution (b) (a similar behavior has been obtained in the same kind of calculations for an infinite step[15]). However, the small difference of energy between them and the fact that experiments are performed at finite temperatures permit us to speculate about the possible coexistence of both solutions at finite temperature. Furthermore, the perfect layered-AF structure of Cr is broken as a consequence of the defect, since atoms at the kink in solution (a) and at the edge in solution (b) display a local moment opposite to the rest of Cr atoms belonging to the same plane. Complex magnetic order of Cr moments close to the Fe substrate has been pointed out by Turtur and Bayreuther in recent experiments on ultrathin Cr films on Fe(100).[11]

In Fig. 2, the results are shown for the most stable magnetic arrangement obtained in the Fe/Cr(107) system. In this case, F coupling between the kink and edge atoms of the Fe overlayer is obtained, in agreement with the tendency between nearest neighbors of Fe. Moreover, a periodicity of two steps is imposed by the AF Cr substrate, as can be seen in Fig. 2. Thus, the sign of the magnetization at the Fe overlayer oscillates from step to step. This spin flop gives support to the fact that the two-layer period oscillation of the exchange coupling between Fe layers observed in Fe/Cr/Fe wedge structures[9,10] is favored by the AF order of the Cr substrate, particularly for large Cr thickness. Furthermore, the total magnetic moment at the Fe overlayer results in zero, in agreement with the total moment measurements of Bayreuther[16] for Fe overlayers on Cr. Frustration effects are also present in this case, since the Fe atom at the edge is ferromagnetically coupled with two nearest-neighbor Cr atoms at the subsurface layer. Another two (less stable) magnetic arrangements are present for this system. One of them appears when Fe atoms at the kink and edge change the sign of their local magnetization.[13] In the third solution, the local magnetic moment in all Fe atoms points in the same direction, so that an F iron overlayer is obtained. However, the strong frustration present in this case give rise to a difference in energy of 0.004 eV per atom with respect to the most stable one.

The present work shows that if a steplike defect is considered at the surface or interface of these materials, various magnetic configurations can be found and, in some cases, with small differences in energy between them. Due to the strong environment dependence of the magnetic properties, one expects the surface reconstruction of the presented stepped systems to have an important influence in the magnetic arrangement. Thus, for a full understanding of the experimental observations,[11,16] the geometrical structure has to be treated in the same level as the electronic structure in the model calculations. Here, we have studied the effect of the steps, b t other phenomena like the mentioned reconstruction, interdiffusion, or local inclusions of other surface orientations deserve to be also analyzed. Calculations along these lines are in progress.

Influence of Cr growth on exchange coupling in Fe/Cr/Fe(100) (invited) (abstract)

Joseph A. Stroscio, D. T. Pierce, J. Unguris, and R. J. Celotta
Electron Physics Group, National Institute of Standards and Technology, Gaithersburg, Maryland 20899

The giant magnetoresistance and the interlayer exchange coupling between magnetic layers separated by nonmagnetic spacer layers are sensitive to the roughness at the interfaces in multilayer magnetic structures. We present scanning tunneling microscopy (STM) measurements of the thickness fluctuations in Cr films grown at different temperatures on near-perfectly flat Fe(100) whiskers and correlate these results with our scanning electron microscopy with polarization analysis (SEMPA) measurements of the oscillations of the exchange coupling in Fe/Cr/Fe(100) structures grown at similar temperatures. Layer-by-layer growth was observed by STM for Cr deposition on an Fe substrate at deposition temperatures greater than 300 °C. The SEMPA measurements of the Fe overlayer magnetization as a function of Cr spacer layer thickness for Cr growth at this temperature could be simulated well by oscillatory coupling with periods $2.105 \pm 0.005d$ and $12 \pm 1d$, where d is the layer spacing. Rougher Cr growth, limited by diffusion kinetics, is observed at lower temperatures, giving a distribution of thicknesses in the growth front. We modeled the Fe magnetization for lower temperature Cr growth by assuming that the exchange coupling at each discrete Cr thickness is the same as found for layer-by-layer growth. The total coupling at each average Cr spacer layer thickness was determined by adding the weighted contribution to the coupling from each Cr layer thickness contributing to the average thickness. Very good agreement was obtained with the SEMPA measurement of the Fe overlayer magnetization for Cr growth at lower temperatures without including other consequences of roughness at the interface, such as the breakdown of translational invariance.

Exchange magnetic coupling through nonmagnetic insulator spacers (abstract)

Shufeng Zhang
Department of Physics, New York University, New York, New York 10003

Interlayer magnetic coupling has been found in magnetic multilayers with nonmetallic spacers.[1,2] In metallic spacers the coupling is provided by electrons at the Fermi sphere; in nonmetallic spacers the coupling is either due to localized states or to thermally activated conduction electrons (or by other external means, e.g., photon exposure). We calculate this coupling by extending the RKKY-like interaction to insulator bands at finite temperatures. Since the length scale $1/k_F$ (where k_F is the Fermi wave vector) that governs the oscillatory behavior of coupling for metallic spacers does not appear in the present case, the form of the coupling with respect to the thickness and temperature is quite different for metallic and for nonmetallic spacers. We study the interlayer coupling for two types of spacers, crystalline, and noncrystalline (amorphous) semiconductors. For the former, the conduction (or valence) bands are well-defined and the calculation of the coupling is rather straightforward. The coupling at room temperature oscillates from ferromagnetic to antiferromagnetic and back to weakly ferromagnetic as the thickness of the spacer layer increases. The antiferromagnetic coupling only exists in a narrow range of the thickness of the spacer layer. For an amorphous semiconductor spacer, the coupling can be expressed in terms of localized states. Within the variable range hopping picture, one can relate these localized states to the localization length. We discuss the range and temperature dependence of the coupling for amorphous spacers. Our calculations are in good agreement with experimental results.

Fabrication of magnetostrictive actuators using rare-earth (Tb,Sm)-Fe thin films (invited)

T. Honda
Materials Research Laboratory, Tokin Corporation, 6-7-1 Koriyama, Taihaku-ku 982, Japan

K. I. Arai and M. Yamaguchi
Research Institute of Electrical Communication, Tohoku University, 2-1-1 Katahira, Aoba-ku Sendai 980-77, Japan

A new concept is proposed for the microactuation based upon magnetostriction. Magnetostrictive bimorph cantilever actuators and a traveling machine, composed of the magnetostrictive amorphous Tb-Fe and Sm-Fe thin films on a polyimide substrate, were fabricated. These actuators moved without power supply cables. The 3-mm-long cantilever actuator exhibited the large deflection above 100 μm in as low a magnetic field as 300 Oe and above 500 μm at resonant frequency in an alternating magnetic field of 300 Oe. Such unique characteristics suggest that magnetostriction is useful as the driving force of the microactuator.

I. INTRODUCTION

A high-performance microactuator is required for the microelectromechanical system (MEMS). Several driving principles for the microactuator such as electrostatic force, electromagnetic force, piezoelectric effect, thermal expansion, and shape memory effect have been proposed up to now. In principle, electrostatic force devices are favorable for the μm-size actuators,[1] but some practical applications require larger mechanical forces than those obtained by electrostatic forces.

On the other hand, the electromagnetic force, which is predominant in a macroworld, had been considered to be unsuitable for the microactuator because it is a body force; however, recent developments of the three-dimensional micromachining techniques have enabled magnetic microstructures having enough volume to generate large mechanical forces. As a result, some magnetic microactuators have been demonstrated.[2,3] In the future, the magnetic microactuator is expected to play an important part of the MEMS.

In this article we propose a new concept for the microactuation based upon magnetostriction. The advantages of the magnetostrictive actuator are as follows: (1) The combination of a positive magnetostrictive material and a negative one enables a large deflection; (2) no power supply cable is required for its actuation because it is driven by external magnetic fields.

In spite of these advantages, only an in-pipe mobile robot made of a "bulk" magnetostrictive material has so far been reported.[4] Taking account of miniaturization and integration with other microelements, a magnetostrictive "thin film" should be used for the microactuator. In order to develop such thin-film actuators, we needed magnetic thin films with large magnetostriction in low magnetic fields. Here we used amorphous Tb-Fe thin films having positive magnetostriction and amorphous Sm-Fe thin films having a negative one. Both films exhibited a large magnetostriction of above 10^{-4} in low magnetic fields.[5,6]

In this article we fabricated two kinds of magnetostrictive "bimorph" cantilever actuators of different sizes and a traveling machine using the Tb-Fe and Sm-Fe thin films. We examined their basic properties and discussed their merits for the microactuators.

II. MAGNETOSTRICTIVE MATERIALS

The magnetostriction of the conventional materials such as Ni, Fe-Al, and amorphous Fe-Si-B is only $30–40\times10^{-6}$. On the other hand, some of rare-earth–transition-metal (RE-TM) crystalline alloys have very large magnetostriction above 10^{-3}. In particular, $TbFe_2$ has the largest positive magnetostriction and $SmFe_2$ has the largest negative one;[7] however, they have very large magnetocrystalline anisotropies and in general need large magnetic fields to saturate the magnetostriction. In order to reduce the magnetocrystalline anisotropy, two methods can be used: One is to alloy positive and negative magnetocrystalline materials such as

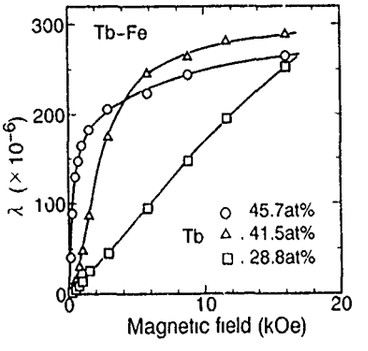

FIG. 1. Applied magnetic-field dependence of the magnetostriction for Tb-Fe thin films

 0021-8979/94/76(10)/6994/6/$6.00 © 1994 American Institute of Physics

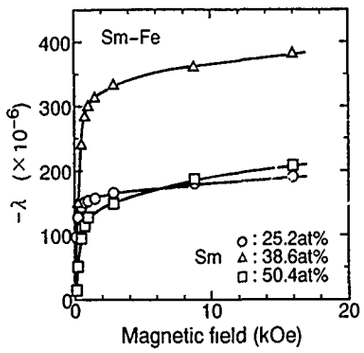

FIG. 2. Applied magnetic-field dependence of the magnetostriction for Sm-Fe thin films.

(Tb,Dy)Fe_2 and the other is to prepare amorphous state materials. In our study we applied the latter, because amorphous RE-TM thin films are easily obtained by a sputtering technique.

Details of the magnetic properties of the amorphous Tb-Fe and Sm-Fe thin films have been already reported in our previous articles.[5,6] In this section, we explain the outline.

Figure 1 shows the applied magnetic-field dependence of the magnetostriction for the Tb-Fe thin films having different compositions. The magnetostriction at 16 kOe exhibited large values above 250×10^{-6} in a wide composition range for 28–46 at. % Tb; however, the low-magnetic-field characteristics largely depended on the film composition because of the composition dependence of the magnetic anisotropy.

The films with 18–40 at. % Tb content had perpendicular magnetic anisotropy and needed high magnetic fields to saturate in-plane magnetization. On the other hand, the films with above 45 at. % Tb content had in-plane magnetic anisotropy. In this case, the in-plane magnetization increased rapidly in low magnetic fields, and accordingly the magnetostriction increased in the same manner. The saturation magnetostriction decreased with increasing Tb content above 50 at. % Tb; therefore, we used the 45–50 at. % Tb-Fe thin films for further examinations.

Figure 2 shows the applied magnetic-field dependence of the magnetostriction for the Sm-Fe thin films having different compositions. The magnetostriction increased rapidly in low fields regardless of Sm content because Sm-Fe thin films always had in-plane magnetic anisotropy. The maximum absolute values of $250–300\times10^{-6}$ at 1 kOe and $300–400\times10^{-6}$ at 16 kOe were obtained at 30–40 at. % Sm. In this experiment we chose the 30–40 at. % Sm-Fe films for the fabrication of actuators.

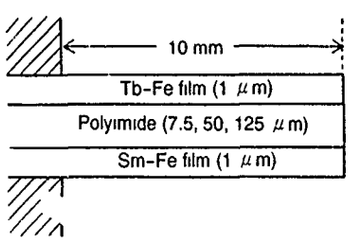

FIG. 3. Side view of the cantilever actuator.

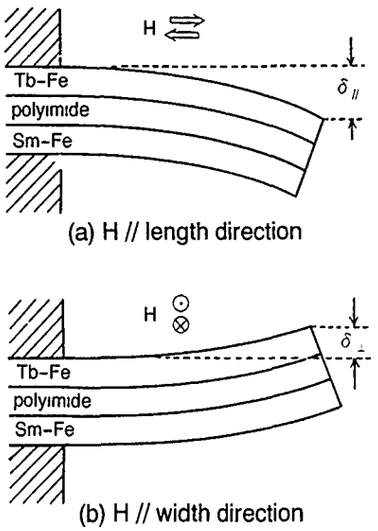

FIG. 4. Actuation behavior of the magnetostrictive bimorph cantilever.

III. DEVICE CONCEPT

Figure 3 shows the side view of the magnetostrictive bimorph cantilever. On a surface of a polyimide substrate, which has low elastic stiffness and high thermal stability, the Tb-Fe film is sputtered and on the opposite surface the Sm-Fe thin film is sputtered.

Figure 4 shows the actuation behavior of the magnetostrictive bimorph cantilever. When a magnetic field is applied along the cantilever length direction, the Tb-Fe film expands and the Sm-Fe film contracts in the length direction and as a result the cantilever deflects downward [Fig. 4(a)]. Next, when a magnetic field is applied along the cantilever width direction, the Tb-Fe film contracts and the Sm-Fe film expands in the length direction and then the cantilever deflects upward [Fig. 4(b)].

A bending behavior for the cantilever with composite structure such as a thermally excited bimetal cantilever[8] and a piezoelectric bimorph cantilever[9] has been analyzed using a classical method. Therefore, we applied this theory to the magnetostrictive cantilever and described below.

For the cantilever of total thickness h and length L, let the z direction be the thickness dimension and a neutral axis be located at $z=0$. We defined n $(0<n<1)$ to satisfy the condition that the upper surface and the lower one are located at $z=nh$ and $z=(n-1)h$, respectively. The neutral axis can be found from

$$\int_{(n-1)h}^{nh} E(z)z\,dz=0, \tag{1}$$

where $E(z)$ is Young's modulus as a function of thickness. In this article we assume that Tb-Fe and Sm-Fe films have the

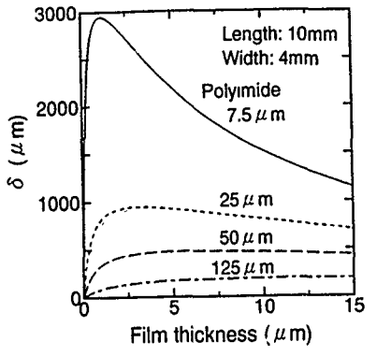

FIG. 5. Calculated deflection of magnetostrictive bimorph cantilevers as a function of thickness of each magnetic layer.

same Young's modulus and thickness; therefore, the neutral axis is located in the geometric center for a bimorph structure, that is, $n=0.5$.

When a magnetic field is applied along the length direction, the radius of bending curvature R caused by magnetostriction can be expressed by

$$R=\frac{\int_{(n-1)h}^{nh}E(z)z^2\,dz}{\int_{(n-1)h}^{nh}E(z)\lambda(z)z\,dz}, \tag{2}$$

where $\lambda(z)$ is the strain in the length direction caused by magnetostriction as a function of thickness and magnetic field. The tip deflection of the cantilever δ is

$$\delta=R[1-\cos(L/R)]. \tag{3}$$

In our study, R is much larger than L. Therefore, Eq. (3) can be approximated by

$$\delta=L^2/2R. \tag{4}$$

This equation indicates that the deflection decreases strongly with decreasing the cantilever length.

Next, when a magnetic field is applied along the width direction, we approximated that the strain in the length direction by magnetostriction is $-\lambda(z)/2$. Accordingly, the cantilever deflects in the opposite direction and the tip deflection is a half of that expressed in Eq. (4). When the cantilever is driven in rotating in-plane magnetic fields, the total deflection is the sum of the deflection caused by a magnetic field along the length direction and that by a magnetic field along the width direction.

Figure 5 shows the calculated tip deflection for the bimorph cantilever with a length of 10 mm as a function of thickness of each magnetic film layer when it is driven in a rotating in-plane magnetic field. In this calculation, we assumed the magnetostriction values of $\lambda_{Tb\text{-}Fe}=150\times10^{-6}$ for Tb-Fe films and $\lambda_{Sm\text{-}Fe}=-250\times10^{-6}$ for Sm-Fe films. These are typical experimental values obtained at 1 kOe on a glass substrate. The calculated deflection increases with decreasing the substrate thickness and that each substrate has the optimum thickness of the magnetic film to exhibit the maximum deflection. This calculation excludes the stress and strain in the width direction and the magnetic torque described later, but is effective to estimate the brief operation of the cantilever.

IV. FABRICATION

The amorphous Tb-Fe and Sm-Fe thin films were prepared by the rf magnetron sputtering method. They were deposited to a thickness of 1 μm on each surface of a rectangular polyimide substrate. The sputtering target used was composed of a pure Fe plate (3 in. diameter) and small Tb or Sm chips. The film composition was 45–50 at. % Tb for the Tb-Fe films and 30–40 at. % Sm for the Sm-Fe films as mentioned above. rf input power was 200 W, and Ar gas pressure was 4–10 mTorr for the Tb-Fe films and 10 mTorr for the Sm-Fe films. During sputtering, the substrate was water cooled. In order to prevent the oxidation of the magnetostrictive thin films, SiO_2 films with a thickness of 0.05–0.1 μm were coated on them.

After deposition, we clamped one end of the substrate and then obtained the magnetostrictive cantilever actuators as shown in Fig. 3. In this experiment, we fabricated two kinds of the cantilever actuators. One was a 10-mm-long cantilever using a commercial polyimide film with a thickness of either 7.5, 50, or 125 μm. The other was a microcantilever with a length of 3 mm using a 3-μm-thick polyimide film. This very thin substrate was made from 7.5-μm-thick polyimide by reactive-ion etching (RIE) using O_2 gas. The tip deflection of the cantilever was measured by both a three-terminal capacitance method[10] and direct observation using the optical microscope.

V. RESULTS AND DISCUSSION

A. Magnetic properties on a polyimide substrate

Before fabrication of the actuators, we investigated the magnetic properties of the Tb-Fe and Sm-Fe films sputtered on the polyimide substrate.

Figure 6 shows the magnetization curves of (a) Tb-Fe thin films on the glass substrate, (b) the 50-μm-thick polyimide substrate, and (c) the 3-μm-thick polyimide substrate. The 3-μm-thick substrate was the thinnest for our present techniques. The in-plane magnetization on the glass substrate increased rapidly in low magnetic fields, while that on the 50-μm-thick polyimide required high magnetic fields to saturate. This result suggests that we could not obtain the large magnetostriction in low magnetic fields when the 50-μm-thick polyimide was used. This change of the magnetic properties was caused by the large compressive stress in the Tb-Fe film with large positive magnetostriction. We think that this compressive stress was generated by the difference of the thermal expansion and/or the thermal contraction of the polyimide during sputtering; however, the magnetic properties on the 3-μm-thick polyimide was similar to those on the glass substrate. The stress in the Tb-Fe film from the substrate decreased with decreasing the thickness of the polyimide substrate.

On the other hand, the magnetic properties of the Sm-Fe films were less dependent on the substrate material, compared with those of Tb-Fe films. It seems that the compressive stress hardly influenced the magnetic properties of the Sm-Fe film because of negative magnetostriction.

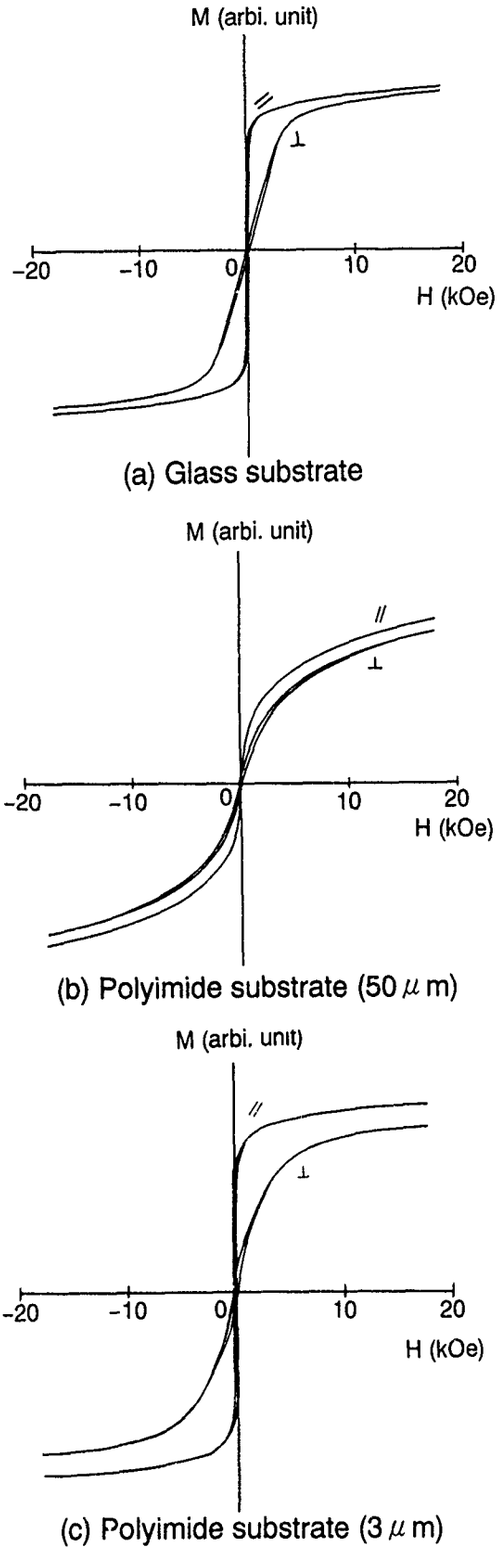

FIG. 6. Magnetization curves of Tb-Fe films

Generally, magnetic properties of the magnetostrictive material are greatly influenced by the stress. It is necessary to pay attention to the stress generated during the deposition and the micromachining process.

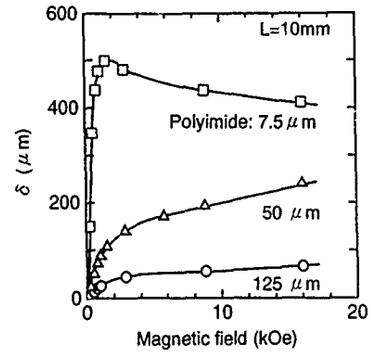

FIG. 7. Applied magnetic-field dependence of the deflection for 10-mm-long cantilevers.

B. 10-mm-long cantilever

In this subsection we examined the basic properties of the magnetostrictive cantilever. The cantilevers were 10 mm long and 4 mm wide.

Figure 7 shows the applied magnetic-field dependence of the deflection, when the cantilevers were driven in a rotating in-plane magnetic field. It is seen that each cantilever exhibited the large deflection in relatively low magnetic fields and that the deflection increased with decreasing the substrate thickness. The deflection of the cantilever using a 7.5-μm-thick polyimide exhibited the maximum value of approximately 500 μm at 1–1.5 kOe.

In the case of using the 7.5-μm-thick polyimide, however, the deflection decreased at high magnetic fields above 2 kOe. This was due to the magnetic torque generated by the large directional difference between the magnetic moment in the films and the applied magnetic field, when a high magnetic field was applied along the length direction as shown in Fig. 4(a). We must design the magnetostrictive actuator, taking account of both the amplitude and the direction of the applied magnetic field.

C. Microcantilever

From the results of the magnetic properties on the polyimide substrate and the 10-mm-long cantilever, we found that a thinner substrate was effective to obtain the large de-

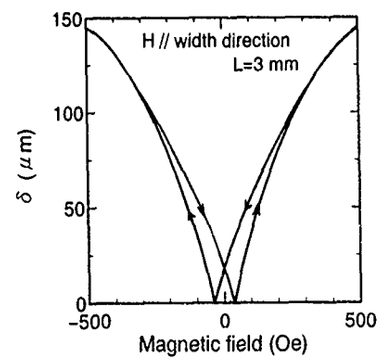

FIG. 8. Applied magnetic-field dependence of the deflection for a 3-mm-long cantilever.

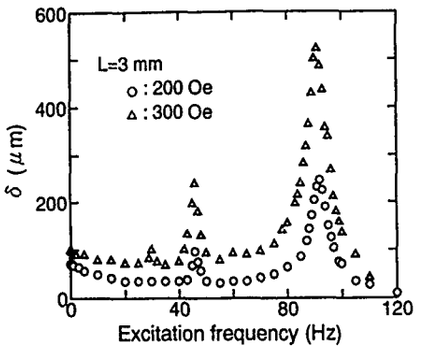

FIG. 9. Excitation frequency dependence of the deflection.

flection. Therefore, we fabricated a trial microcantilever using a 3-μm-thick polyimide substrate. The cantilever was 3 mm long and 0.5 mm wide. In this experiment we examined its hysteresis and dynamic behavior.

Figure 8 shows the hysteresis curve of the tip deflection of the microcantilever when a magnetic field was applied along the width direction, where the deflection was little influenced by the magnetic torque. It exhibited a large deflection above 100 μm at as low a field as 300 Oe. This deflection was equivalent to more than 1 mm of the 10-mm-long cantilever as seen from Eq. (4); besides, this microcantilever had relatively small hysteresis. Such characteristics of the cantilever actuator were suitable for application as a micropositioning device.

Figure 9 shows the excitation frequency dependence of the deflection when alternating magnetic fields of 200 and 300 Oe were applied along the width direction. Note that the vibrational frequency was double the excitation frequency because the cantilever deflected in the same direction for both positive and negative magnetic fields. The cantilever exhibited the maximum deflection above 500 μm at an excitation frequency of 92 Hz, where the vibrational frequency agreed with its mechanical resonant frequency. This maximum deflection was five times as large as that in a static field. Two small peaks observed around 30 and 45 Hz were caused by the harmonics of the vibration.

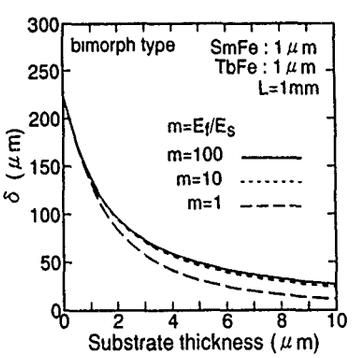

FIG. 10. Calculated deflection of the 1-mm-long cantilever as a function of the substrate thickness.

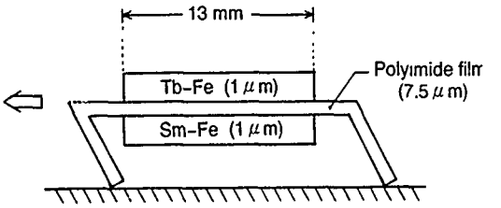

FIG. 11. Schematic view of a traveling machine.

We describe the future direction of the actuator design on the basis of Eq. (3). Figure 10 shows the calculated deflection of the bimorph cantilever with a length of 1 mm as a function of the substrate thickness when it is driven in a rotating in-plane magnetic field. E_f and E_s are the Young's modulus of the magnetostrictive films and substrate, respectively. Note that the deflection was a function of ratio of E_f/E_s. In our experiment, E_f/E_s is about 12 and the magnetostrictive films were supposed to be 1 μm thick and have magnetostriction as in the case of Fig. 5. The deflection increased gradually with decreasing the substrate thickness, and when substrate thickness is zero, that is, a "bimetal" structure composed of the Tb-Fe film and the Sm-Fe film, the predicted deflection exhibits the maximum value of 225 μm.

D. Traveling machine

We fabricated a traveling machine using the magnetostrictive bimorph actuator with 7.5-μm-thick polyimide as shown in Fig. 11. Its two legs at both ends were inclined so that it could travel in one direction. When an alternating magnetic field was applied, it vibrated and traveled in the arrow direction on disk planes as well as inside a quartz tubes (6.5 mm in diameter).

Figure 12 shows the excitation frequency dependence of the average traveling velocity when an alternating magnetic field of 300 Oe was applied along the machine width direction. The traveling machine needed the excitation frequency

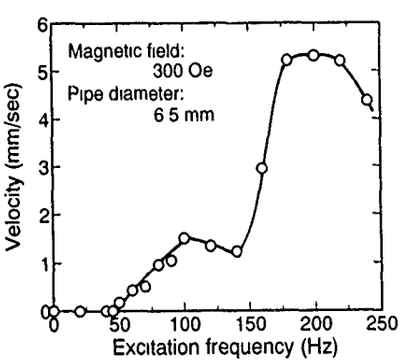

FIG. 12. Excitation frequency dependence of the average traveling velocity.

above 50 Hz to begin to travel and exhibited the maximum speed of approximately 5 mm/s around the mechanical resonant frequency of 200 Hz.

This magnetostrictive traveling machine requires no power supply cables which disturb its actuation in a microworld; therefore, magnetostriction is suitable for the driving force of the traveling micromachine.

VI. CONCLUSIONS

We fabricated cantilever actuators and a traveling machine using magnetostrictive Tb-Fe and Sm-Fe thin films and examined their basic properties. They showed unique characteristics such as large deflection and wireless driving. These results indicate that the magnetostrictive actuation is useful as the driving force of microactuators.

Preparation and applications of magnetostrictive thin films

E. Quandt, B. Gerlach, and K. Seemann
Kernforschungszentrum Karlsruhe GmbH, Institute of Materials Research I, D-76021 Karlsruhe, Germany

Amorphous magnetostrictive films of the binary compound Sm_xFe_{1-x} as well as of the ternary compound $(Tb_yDy_{1-y})_xFe_{1-x}$ were prepared by rf or dc magnetron sputtering using either a multitarget arrangement with pure element targets or cast composite-type targets. The magnetostrictive properties of $(Tb_{0.3}Dy_{0.7})_{0.4}Fe_{0.6}$ and $Sm_{0.4}Fe_{0.6}$ films were investigated in relation to their preparation conditions. Depending upon these conditions (especially upon the deposition rate, the bias voltage, and the Ar sputtering pressure) amorphous films with a giant magnetostriction of about 250 ppm (−220 ppm) at 0.1 T and 400 ppm (−300 ppm) at 0.5 T for the TbDyFe (SmFe) and an in-plane magnetic easy axis could be prepared. In view of applications in microsystem technologies (e.g., pumps, valves, positioning elements) these films have been tested in a simple cantilever arrangement and the predicted deflection of a magnetostrictive actuated membrane has been calculated.

I. INTRODUCTION

Giant magnetostriction in thin films is thought to be a promising actuator mechanism for microactuators. Due to the interest in such applications, research has focused upon materials exhibiting low-field magnetostriction and soft-magnetic properties. During the last few years various attempts have been made to improve the low-field magnetostrictive properties of amorphous rare-earth–Fe films. Successful approaches were to increase the total rare-earth content compared to that of the crystalline phases,[1] to alloy different rare earths to compensate the anisotropy,[2] to adjust the preparation conditions in order to induce tensile film stresses,[3] and to add small amounts of B to change the amorphous state of the films.[4,5]

The present article describes the influence of preparation conditions (sputtering power, Ar sputtering pressure, bias voltage) on the composition, microstructure, and in-plane magnetostrictive properties. Functioning tests and calculations are then discussed which show the behavior of possible actuator components based on these films.

II. EXPERIMENTAL WORK

The binary systems TbFe and SmFe were dc magnetron sputtered by the multitarget arrangement with pure element targets.[1] For the rf or dc magnetron sputtering of the TbDyFe films a cast composite-type target (Degussa AG/Leybold Materials) was used. The Tb/Dy ratio of this target, $(Tb_{0.3}Dy_{0.7})_{0.42}Fe_{0.58}$, was chosen in accordance with results on the rare-earth anisotropy compensation composition at room temperature[6] and its total rare-earth content according to results that have been reported previously.[1] Typical deposition rates, with an Ar sputtering pressure of 0.4 Pa, are 3 μm/h for the multitarget arrangement at a distance of 100 mm and 16 μm/h for the composite-type target at 300 W and a distance of 50 mm.

Composition was determined by wavelength-dispersive x-ray microanalysis (WDX), and depth profiles were obtained using Auger electron spectroscopy (AES). The microstructures were investigated by x-ray diffraction (XRD) and transmission electron microscopy (TEM). In-plane magnetostriction was measured by the common cantilevered substrate technique, polarization by a vibrating sample magnetometer (VSM), and Curie temperature by a superconducting quantum interference device (SQUID) magnetometer. The film stress was calculated by measuring the difference of the curvature of the uncoated and coated Si substrate using a long-scan profiler.

III. RESULTS

A. Materials

The magnetron sputtering deposition of the rare-earth–Fe films onto unheated SiO_2, Si, or metal substrate resulted in amorphous, dense films with thicknesses ranging between 1 and 15 μm. A dependence of the magnetostriction upon film thickness was not observed within this range. The time-dependent oxidation was investigated at room temperature for TbFe and TbDyFe films. Although both these films have the same total rare-earth content, they exhibited slightly different oxidation dependencies (Fig. 1). AES depth profiles indicated that the rare-earth oxide formed at the film surface, which would tend to slow further oxidation within the sample, is more stable in the case of the TbFe compared to

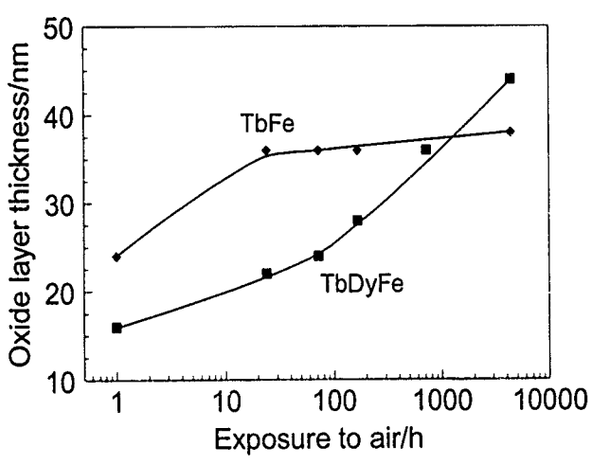

FIG. 1 Time dependence of the oxidation zone thickness obtained by AES depth profiling.

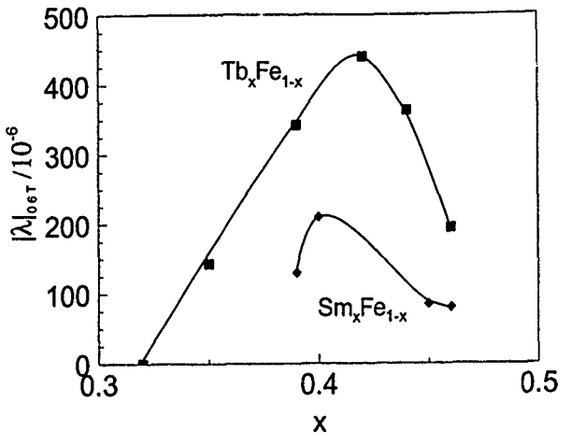

FIG. 2. Magnetostriction measured at an external field $\mu_0 H = 0.6$ T applied parallel to the film plane vs the rare-earth content of amorphous Tb_xFe_{1-x} and Sm_xFe_{1-x} films.

the TbDyFe film. Small-angle XRD revealed a crystalline nature for the oxidized region. This is in contrast to results reported previously.[7]

As was the case with the Tb_xFe_{1-x} films,[1] the maximum of the magnetostriction of the Sm_xFe_{1-x} films was found to be at a rare-earth content of about 40 at. % (Fig. 2). Compared to the TbFe films, however, the rare-earth anisotropy is significantly lower. This results in a higher low-field magnetostriction. The influence of the sputtering parameters has been investigated with the composite-type target $[(Tb_{0.3}Dy_{0.7})_{0.42}Fe_{0.58}]$ in more detail. Dramatic changes in the magnetostriction were observed in the low-field region (up to 0.15 T) which is of special interest for applications in microsystem technology. At 0.5 T all these films show a comparable magnetostriction of about 400 ppm. Best results were obtained for dc as opposed to rf magnetron sputtering, an Ar sputtering pressure of 0.4 Pa [Fig. 3(a)], an rf bias of 160 V [Fig. 3(b)], and a sputtering power of 300 W [Fig. 3(c)]. The results illustrated the dominant influence of the bias voltage on low-field magnetostrictive properties, which was also observed for the multitarget sputtering of $Sm_{0.4}Fe_{0.6}$ films (Fig. 4) even if the low-field improvement is less pronounced compared to TbDyFe films. The variations of the sputtering parameters have almost no influence on the chemical composition and on the Curie temperature of about 350 K. Although XRD and TEM investigations also give no evidence of a changed microstructure—due to temperature-annealing ongoing deposition as a result of the altered sputter conditions—the Ar-ion bombardment related with the applied bias voltage changes the magnetic anisotropy. This results in an in-plane magnetic easy axis for the optimized TbDyFe films (Fig. 5) whereas TbDyFe films sputtered without bias show perpendicular anisotropy.[1] In comparison to dc-sputtered TbDyFe films[3] the thermal induced stress is comparably low (100 GPa) and further reduced to about 40 GPa as a result of the applied bias voltage of 160 V. In this case the magnetoelastic energy due to the film stress is lower than the form anisotropy energy leading to an in-plane easy magnetization.

B. Applications

Sputtering deposition of magnetostrictive thin films in combination with microstructuring by etching or sputtering through masks provides a promising method for the integra-

tion of actuator components in microsystems by batch processes. With this in mind, materials relevant to microengineering applications as Si and various metals suitable for the lithography, electroforming, and plastic molding (LIGA)[8] process were chosen as substrates for prototype components. Using the optimized TbDyFe film of 10 μm thickness a deflection of a Si (100) cantilever (20 mm×5 mm×50 μm) of about 200 μm at a field of 0.05 T could be obtained (see Fig. 6). This low-field deflection is considerably greater than that reported for 50-μm-thick polyimide samples.[9] For micropump and microvalve applications membranes, in addition to cantilevers, are important components. Finite-element-method (FEM) calculations of a magnetostrictive coated metal membrane predict a maximum deflection of 75 μm for a 12.5-mm-diam membrane with both 4 μm thickness of the membrane and the coating. Using the optimized films the required magnetostriction of 200 ppm already is obtainable in a field of 0.05 T.

Magnetostriction in TbDyFe thin films

P. J. Grundy, D. G. Lord, and P. I. Williams
Joule Physics Laboratory and Science Research Institute, University of Salford, Greater Manchester M5 4WT, United Kingdom

Magnetization and magnetostriction in amorphous binary TbFe and DyFe and amorphous and polycrystalline, ternary $(Tb_xDy_{1-x})_yFe_{100-y}$ thin films have been investigated. The measurements reflect the compositional dependence of the easy direction of magnetization in the films. In plane magnetostrictions of over 300×10^{-6} were measured for some of the amorphous TbFe and TbDyFe films and values greater than 750×10^{-6} were obtained in polycrystalline TbDyFe films near to the Terfenol composition.

I. INTRODUCTION

Rare-earth–transition-metal (RE-TM) alloy films deposited from the vapor are usually amorphous, and postdeposition annealing or deposition onto a heated substrate is required to effect crystallization. Films containing heavy rare earths (e.g., Tb, Dy) are ferrimagnetic and can exhibit perpendicular anisotropy, magnetization compensation, and large coercivities. In common with others[1–3] we find that these interesting characteristics in the binary alloys are complemented by exceptional magnetostrictive properties at relatively low magnetic fields. We also find that very large magnetostrains are obtained in some ternary TbDyFe alloys in both the amorphous and crystalline forms.

II. EXPERIMENT

The films were deposited from a triode source in a cryopumped sputter-deposition system. The target consisted of a $150\times50\times6$ mm^3 rectangular Fe plate containing 33 10-mm-diam holes. With the holes occupied by Tb, Dy, or Fe inserts this arrangement allowed for the deposition of a continuous range of RE_xTM_{100-x} alloys with $5<x<50\%$. The deposition rate was typically 50 nm min^{-1} and the thickness of the resulting films was ~1 μm. Crystalline films were obtained by deposition onto heated glass substrates. The magnetic properties of the films were obtained by vibrating sample magnetometry (VSM) (up to 1000 kA m^{-1}) and their magnetostrictions were measured on an optical cantilever system with a sensitivity of 10^{-7} in fields up to 350 kA m^{-1} (Ref. 4). Young's modulus values for the films (in zero field) were calculated from load/indentation curves obtained on a sensitive microhardness instrument.

III. RESULTS AND DISCUSSION

The compositions of the films were obtained from Rutherford backscattering and x-ray microanalysis measurements. They were found to be near to the designed composition and to be uniform to better than 1 at. % over the area of the film (20×5 mm^2); however, a small composition gradient was measured through the thickness of the films, typically 2 at. % μm^{-1}. This gradient was probably caused by a gradual decrease in the sputtering yield from the RE inserts with time.

Amorphous alloy films in the two binary series Tb_xFe_{100-x} and Dy_xFe_{100-x} and the ternary $(Tb_xDy_{1-x})_{33}Fe_{67}$ and $(Tb_xDy_{1-x})_{43}Fe_{57}$ series were deposited. The ternary $RE_{33}Fe_{67}$ series was chosen because the equivalent bulk polycrystalline compositions are known to show interesting magnetic behavior. The ternary $RE_{43}Fe_{57}$ films were also deposited because of the large magnetostrictions found in the amorphous phase.[5] It was observed that an excess of RE was necessary for the formation of crystalline $REFe_2$; i.e., $Tb_{0.27}Dy_{0.73}Fe_2$, when deposited onto a heated (350 °C) substrate.

Figure 1 gives the compositional dependence of magnetization for amorphous Tb_xFe_{100-x} films. The results agree reasonably well with published data.[6–8] The different symbols indicate the effective easy direction in the films which varied with composition. In the range $15<x<40$ the strong perpendicular anisotropy and low magnetization ensured an easy direction of magnetization normal to the film plane. As expected, the coercivity peaks at the room-temperature compensation composition (RTCC). The compositional dependence of magnetization and coercivity in Dy_xFe_{1-x} follows the same pattern with generally smaller values of these two parameters.[5]

The magnetizations of the amorphous ternary $(Tb_xDy_{1-x})_{33}Fe_{67}$ and $(Tb_xDy_{1-x})_{43}Fe_{57}$ (i.e., $\simeq REFe_2$ and RE_3Fe_4) alloys are shown in Fig. 2 as a function of composition x. The easy direction of magnetization of the amorphous $RE_{33}Fe_{67}$ films was normal to the film plane; its value increases as the proportion of Tb increases. The $RE_{43}Fe_{57}$ alloys are at compositions well away from the RTCC and were almost magnetically equiaxed; their magnetization also varied linearly with x but with a greater rate of increase. Also shown is the compositional dependence of M_s for polycrystalline films which contained randomly oriented Laves $REFe_2$ crystallites, and small grains of Fe, excess RE, and RE oxides at concentrations of a few percent.[4] In the case of the crystalline film there is a departure from linearity with an apparent maximum in the magnetization for $25<x<35$. This is associated with the anisotropy minimum at $x=0.27$ (Ref. 9) near the composition of bulk Terfenol

The magnetostrictions of the films were calculated from the bending of the film+substrate cantilever using bending-beam theory.[4,10] Measurements of the magnetostrains λ from fields applied along $\lambda_\parallel$ and at right angles λ_n to the cantilever length can be related, with particular assumptions,[4] to the saturation magnetostriction λ_s as $\lambda_s=2(\lambda_\parallel-\lambda_n)/3$. Figure 3 shows $\lambda_\parallel$ for the amorphous Tb_xFe_{100-x} binary alloys. Values in the range $15<x<35$ are limited by the difficulty of

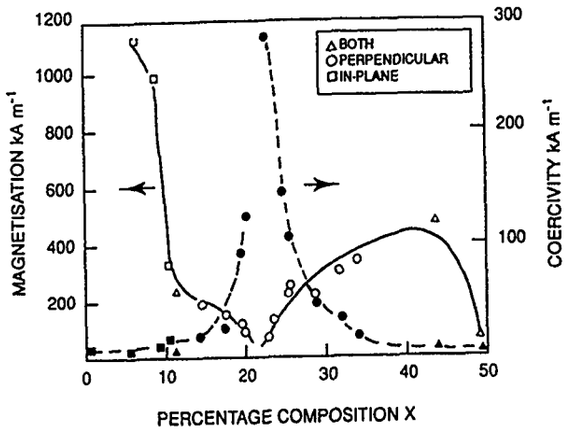

FIG. 1. The magnetization (open symbols) and coercivity (solid symbols) of amorphous Tb_xFe_{100-x} films as a function of x measured with the field applied normal to, in the film plane, and in either direction.

magnetizing the films to saturation in the modest fields used ($\approx$350 kA m^{-1}). For $x>35$, $\lambda_{\|}$ increases to a maximum and then decreases towards the composition ($x\approx50$) with a Curie point below room temperature. We include data from several other investigations.[1,2,11] The general trend of the results is the same; the scatter arises from many factors, such as different deposition techniques, film thickness, and methods of characterization. Magnetostriction values for the Dy_xFe_{100-x} films are much smaller and peak at a value of 60×10^{-6} at $x\approx30$. They agree reasonably well with published data.[3]

Magnetostrains in the amorphous ternary $RE_{33}Fe_{67}$ alloys were found to be small and of the order of $20-40\times10^{-6}$ with no obvious compositional trend. This was possibly accounted for by the inability of the maximum applied field to

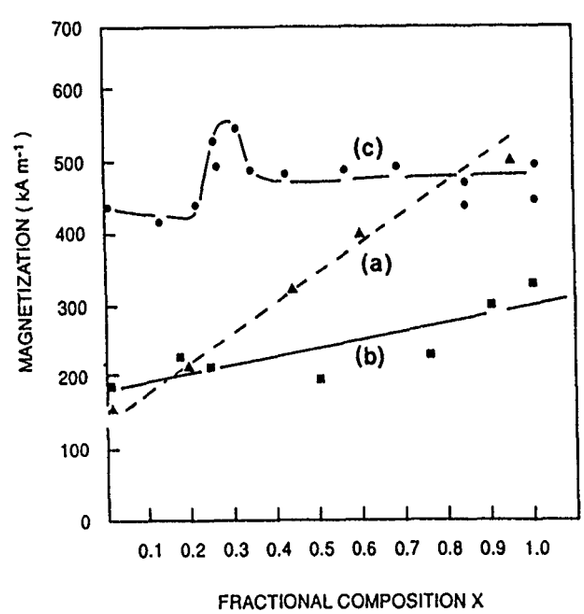

FIG. 2. The compositional dependence of magnetization of (a) amorphous $(Tb_xDy_{1-x})_{43}Fe_{57}$ films and (b) and (c) amorphous and polycrystalline $(Tb_xDy_{1-x})_{33}Fe_{67}$ films.

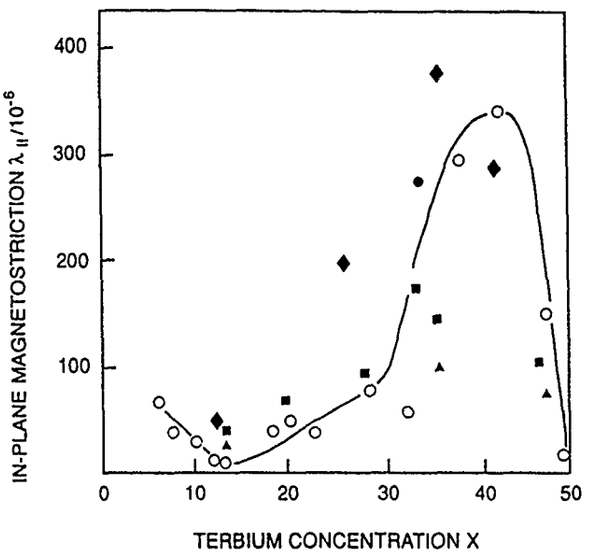

FIG. 3. In-plane magnetostriction values for amorphous Tb_xFe_{100-x} films (at 350 kA m^{-1}). Open symbols this investigation, (▲) and (■) Ref. 1 at 320 and 1280 kA m^{-1}, (●) Ref. 10, and (♦) Ref. 2.

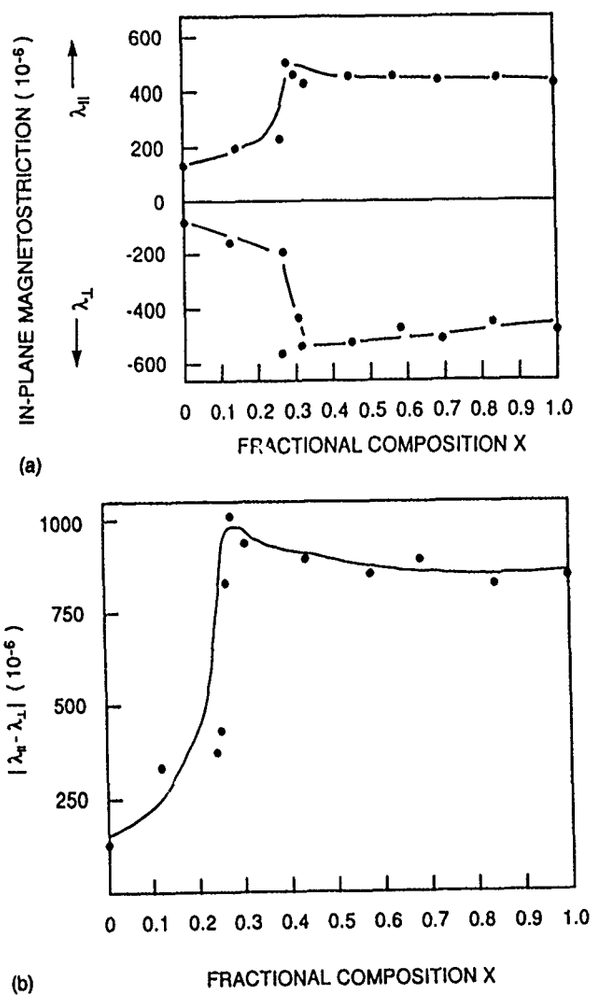

FIG. 4. Compositional dependence of (a) parallel $\lambda_{\|}$ and normal λ_n magnetostrictions and (b) in-plane magnetostrictions for polycrystalline $(Tb_xDy_{1-x})_{33}Fe_{67}$ films.

saturate in plane these films with perpendicular anisotropy. The potential of the amorphous alloy equivalent in composition to crystalline Terfenol could, therefore, not be tested. The $RE_{43}Fe_{57}$ alloys could be magnetized in plane although not to saturation. Values of $\lambda_{\parallel}$ show an increase from the Dy binary to the Tb binary composition with the maximum value of $\simeq 350\times10^{-6}$ obtained for $Tb_{43}Fe_{57}$ ($x=1$) being very close to the peak value shown in Fig. 3.

Parallel and normal magnetostrictions, $\lambda_{\parallel}$ and λ_n, for polycrystalline films containing $(Tb_xDy_{1-x})Fe_2$ phases are shown in Fig. 4(a). The fact that $\lambda_{\parallel} \neq -2\lambda_n$ implies a stress-induced alignment of domains along the cantilever length on deposition. This departure from a random alignment of domains results in a relatively large λ_n because domains are rotated through a larger angle in the transverse field. The general features of both curves, in particular the rise to a maximum or negative minimum at $x \simeq 0.3$ and the plateaux to $x=1$, are reflected in Fig. 4(b) which gives the planar magnetostriction $|\lambda_{\parallel}-\lambda_n|$. The planar magnetostriction is, in principle, equal to $3\lambda_s/2$, but not here as the films were not saturated. The maximum and minimum occur in the region of anisotropy compensation, and the plateau, rather than a rise, in magnetostriction from $x=0.3$ onward is possibly due to a varying value of E_f (Young's modulus) for the film. E_f is included in the formula for calculating λ and a positive ΔE_f near $x=0.3$ would reduce our calculated value of λ. The magnitude of ΔE_f ($\Delta E_f \propto \lambda^2$) can be quite large and a value of $\simeq 140\%$ has been reported[9] for bulk Terfenol over the range of applied field used in this investigation. Notwithstanding these uncertainties, the results presented here show that the planar magnetostriction of polycrystalline TbDyFe thin-film alloys reaches considerable values in fairly small magnetizing fields, with a maximum of $\simeq 1000\times10^{-6}$ for $Tb_{10}Dy_{23}Fe_{67}$ ($\equiv Tb_{0.3}Dy_{0.7}Fe_2$).

Application of the ratio d/χ to the investigation of magnetization processes in giant-magnetostrictive materials

A. R. Piercy, S. C. Busbridge, and D. Kendall[a)]
Department of Mathematical Sciences, University of Brighton, Brighton, East Sussex BN2 4GJ, United Kingdom

The change in magnetostriction $\Delta\lambda$ with change in magnetization ΔM for domain-wall motion is shown to depend only on the wall type, the magnetostriction constants, and the saturation magnetization and not on the field required to effect the change. The quantity $\Pi=\Delta\lambda/\Delta M$ (or the dynamic equivalent d/χ) is therefore a valuable parameter for use in investigating magnetization processes. Theoretical values of Π are given for different wall processes in $\langle 111\rangle$ and $\langle 100\rangle$ easy materials and used to interpret experimental measurements in different (Tb, Dy, Ho)Fe_2 materials. It is shown that Π vs M curves are more sensitive to the detail of the magnetization process than λ vs M curves. In $\langle 111\rangle$ easy compositions the processes are found to be complex with the combination of wall motion processes changing continuously with increasing magnetization and no region where a single process dominates. In contrast, for $\langle 100\rangle$ easy materials, there is an extended region in which 90° wall processes dominate. In both cases, quasistatic and dynamic processes are shown to be equivalent, independent of temperature, and independent of the frequency and magnitude of the drive field.

I. INTRODUCTION

The magnetic properties of giant-magnetostrictive rare-earth–iron alloys have been extensively investigated for applications as transducer materials. The early work was summarized by Clark[1] and subsequent developments have been reviewed by Jiles.[2] However, relatively little is known about the magnetization processes in these materials and Jiles[2] concludes that study of the processes is a requirement for their further development. This article aims to show that the ratio $\Delta\lambda/\Delta M$, of the change in magnetostriction λ to change in magnetization M, is a valuable parameter for use in investigating magnetization processes.

It is widely accepted that the task of identifying magnetization processes from curves of M (or λ) against applied field H is intractable because of extrinsic effects which limit rotation and domain-wall motion. These effects are generally not only unknown but also vary from point to point in a real polycrystalline material and consequently the field required to effect a change in M or λ is both unknown and nonuniform. Such extrinsic effects do, however, exert a similar influence on both magnetization and magnetostriction and curves of λ vs M have sometimes been used in attempts to infer magnetization processes. We show that the application of such curves is limited because they are relatively insensitive to different model processes and, in addition, their measurement is limited to quasistatic or very low-frequency variations. Conversely, $\Delta\lambda/\Delta M$ is more sensitive and its practical determination is not limited to low frequencies. We have previously reported[3,4] use of $\Delta\lambda/\Delta M$ for the investigation of magnetization processes in giant-magnetostrictive materials and this article aims to provide more detail and to expand its application to a range of conditions and compositions.

II. THEORETICAL VALUES FOR $\Delta\lambda/\Delta M$

We limit consideration to domain-wall motion processes involving walls separating domains having their magnetizations in directions 1 and 2 specified by the direction cosines l_1,m_1,n_1 and l_2,m_2,n_2, respectively, with the magnetostriction being measured in the direction 0 specified by l_0,m_0,n_0. The usual situation with the rare-earth–iron alloys is that the measurement direction is the axis of a rod-shaped specimen of material with preferred orientation such that $\langle 112\rangle$ is parallel to this axis. We are concerned with the ratio $\Delta\lambda/\Delta M$ for which we use the symbol Π, and note that under conditions of alternating excitation $\Delta\lambda/\Delta M$ is equivalent to d/χ, the ratio of the magnetomechanical d coefficient ($d_{33}=\partial\lambda/\partial H$) to the susceptibility ($\chi=\partial M/\partial H$).

When a domain wall moves through a small fraction F_v of the sample in response to a small change in field ΔH, the direction of the magnetization in the volume swept out changes from 1 to 2 so that the change in sample magnetization is

$$\Delta M=F_v M_s(\cos\theta_2-\cos\theta_1),$$

where θ_1 is the angle between directions 1 and 0 so that $\cos\theta_1=(l_1l_0+m_1m_0+n_1n_0)$ and similarly for θ_2. The corresponding change in magnetostriction is

$$\Delta\lambda=F_v(\lambda_{2,0}-\lambda_{1,0}),$$

where $\lambda_{1,0}$ is the saturation magnetostriction measured in direction 0 when the magnetization lies in direction 1 and is given by

$$\lambda_{1\,0}=(3\lambda_{100}/2)(l_1^2l_0^2+m_1^2m_0^2+n_1^2n_0^2-\tfrac{1}{3})+3\lambda_{111}(l_1m_1l_0m_0+m_1n_1m_0n_0+n_1l_1n_0l_0),$$

Π is then given by

$$\Delta\lambda/\Delta M=(\lambda_{2,0}-\lambda_{1,0})/M_s(\cos\theta_2-\cos\theta_1),$$

which is independent of both F_v and ΔH (and therefore of all extrinsic effects) and depends only on the saturation magnetization, the magnetostriction constants, and the wall type (determined by the directions 1 and 2). The resulting values of Π, normalized to (λ_{111}/M_s), are given for different wall types for ⟨111⟩ easy materials in Table I and for ⟨100⟩ easy materials, with Π normalized to (λ_{100}/M_s), in Table II. In both cases it is assumed that the materials have ⟨112⟩ orientation and only those wall movements that give rise to positive values are included (equivalent negative values also occur).

III. COMPARISON WITH EXPERIMENT

Tables I and II show that only a very few definite values of Π can be measured if domain walls of only one type move. In general it is to be expected that wall motion of several different types will occur and in that case values of Π intermediate between those of Table I (or II) are expected. In comparing these theoretical values of Π with measured values, we refer to Π_{dyn} (for d/χ) for values determined under dynamic (alternating) conditions and to Π_{st} (for $\Delta\lambda/\Delta M$) for those determined under quasistatic conditions.

Quasistatic measurements of (differential) permeability and d coefficient yield values considerably greater than those obtained under alternating excitation and it is not clear, *a priori*, whether these arise from the same, or different, magnetization processes. Figure 1 gives Π_{st} and Π_{dyn} as a function of M for $Tb_{0.20}Ho_{0.80}Fe_2$, which is ⟨111⟩ easy at 20 °C, and clearly shows that the static and dynamic processes are equivalent. It is equally clear that there is no sustained region where walls of only one type move (i.e., where Π is constant at one of the values in Table I) and moreover that the combination of wall processes changes continuously, giving a steadily increasing value of Π.

The corresponding λ vs M curve for this sample is shown in Fig. 2 to illustrate the greater sensitivity of the Π vs M curve. The solid line in Fig. 2 represents a possible theoretical model process in which it is assumed that, initially, all domain directions are equally populated and magnetization proceeds first by 180° domain-wall motion for $M<0.236M_s$, followed by 109° wall motion up to $0.707M_s$. This model appears to provide an approximate fit to the experimental points in Fig. 2 for $M<0.707M_s$ (above this it is necessary to invoke rotation to obtain a fit); however, the variation in Π for this model is that shown by the solid line in Fig. 1 from which it is clear that the model gives a completely inadequate description.

Figure 3 compares Π_{st} and Π_{dyn} for $Tb_{0.27}Dy_{0.73}Fe_2$ at 20 and 70 °C and shows that the static and dynamic processes are similar and are essentially independent of temperature. It is found that the variation of Π with M is qualitatively similar for different (Tb, Dy, Ho)Fe_2 compositions, with zero stress bias, in the ⟨111⟩ easy regime, as shown by Figs. 1 and 3. In contrast, for ⟨100⟩ easy compositions the variation of Π with M is very different, as illustrated for $HoFe_2$ in Fig. 4, although the static and dynamic processes are again equivalent. The broken line in Fig. 4 gives the value

TABLE II. Theoretical values of Π for ⟨100⟩ easy material with measurements made in ⟨112⟩.

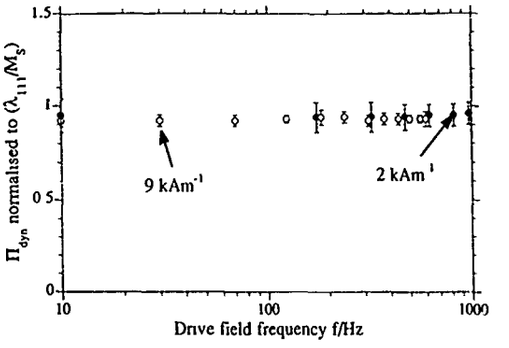

FIG. 5. Variation of Π_{st} and Π_{dyn} with drive field frequency and magnitude for $Tb_{0.27}Dy_{0.73}Fe_2$.

$\Pi=0.612\lambda_{100}/M_s$ (where λ_{100} has been taken as $-\lambda_{111}/3$) appropriate to one type of 90° wall motion and indicates that there is, in this case, an extended region where one domain process dominates. For magnetizations above $0.68M_s$ it is necessary to include rotation processes, as confirmed by domain studies,[5] to explain the observed values of Π.

The technique is also useful for investigating the drive field dependence of the magnetization processes and Fig. 5 shows that Π_{dyn} and, therefore, the magnetization processes are independent of both drive field frequency and magnitude.

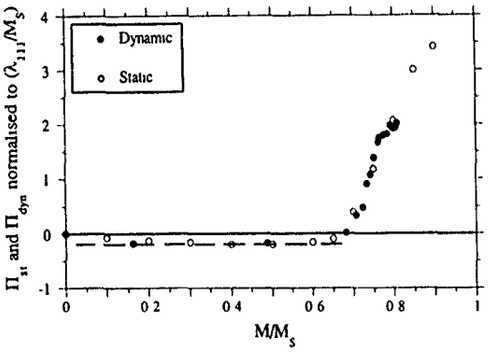

FIG. 4. Variation of Π_{st} and Π_{dyn} with magnetization for ⟨100⟩ easy $HoFe_2$. The broken line gives the value of Π for one type of 90° wall motion.

This frequency independence of Π_{dyn} is found to continue to well above the critical frequency at which eddy-current effects become significant even though, at these higher frequencies, the d coefficient and permeability are diminished.[4]

IV. CONCLUSIONS

It has been demonstrated that the ratio d/χ is a valuable parameter for use in investigating magnetization processes. Comparison of theoretical and measured values of d/χ for ⟨111⟩ and ⟨100⟩ easy giant-magnetostrictive materials has shown that the magnetization processes are generally complex, involving more than one domain-wall process, that quasistatic and dynamic processes are equivalent, independent of temperature and of drive field frequency and magnitude.

Magnetization, Young's moduli, and magnetostriction of rare-earth–iron eutectic alloys with $R=Tb_{0.6}Dy_{0.4}$

A. E. Clark, M. Wun-Fogle, J. P. Teter, J. B. Restorff, and S. F. Cheng
Naval Surface Warfare Center, Code R34, Silver Spring, Maryland 20903-5640

Rare-earth–iron alloys, $R_{0.9}Fe_{0.1}$, $R_{0.72}Fe_{0.28}$, and $R_{0.42}Fe_{0.58}$ ($R=Tb_{0.6}Dy_{0.4}$), containing the R/RFe_2 eutectic composition were prepared by Bridgman and free-standing zone-melting techniques. Magnetization measurements were made in fields up to 800 kA/m between 55 and 300 K. A huge increase in magnetization below 210 K occurs as the R component becomes ordered. At low applied magnetic fields there is clear identification of both the ferromagnetic ordering temperature T_C and the Néel spiral ordering temperature T_N of R. (For $Tb_{0.6}Dy_{0.4}$, $T_C=165$ K, $T_N=210$ K.) Magnetization and magnetostriction measurements reveal very large magnetocrystalline anisotropies for both the R and the RFe_2 components. Unexpectedly, at 77 K, were the rare-earth component of the eutectic system is ordered and the magnetostriction is large ($\lambda^{hy}>0.6\%$), the magnetostriction is largest in the samples containing the largest amount of the RFe_2 phase. Young's modulus measurements reveal the reduction in the stiffness with the addition of the softer rare earth to the stiff RFe_2 compound.

The rare earths Tb and Dy are the elemental components of many giant magnetostrictive materials. In the hexagonal binary alloys, $Tb_xDy_{1-x}(1\leq x\leq 1)$, basal plane magnetostrictions $\lambda^{\gamma 2}$ reach ~1% at 0 K and 0.6 % at 77 K.[1] Although the individual basal plane anisotropies K of Tb and Dy are very large ($K>0$ for Tb; $K<0$ for Dy), K can be minimized and the $\lambda^{\gamma 2}/K$ ratio maximized in the binary Tb_xDy_{1-x} alloy.[2] At 77 K anisotropy compensation occurs for $x\cong 0.6$, the value of x selected for this study. A second important class of materials is the cubic $Tb_xDy_{1-x}Fe_2$ (Terfenol) compounds. For this compound λ_{111} is very large over a wide temperature range.[3] In the Tb-Fe and Dy-Fe alloy systems, a eutectic composition consisting of a rare-earth phase and a rare-earth–Fe_2 phase occurs near 28 at. % Fe.[4] In this article we report magnetic, elastic, and magnetorestrictive properties of the eutectic-containing alloys.

For this study, samples of R, $R_{0.9}Fe_{0.1}$, $R_{0.72}Fe_{0.28}$, $R_{0.42}Fe_{0.58}$, and RFe_2 ($R\equiv Tb_{0.6}Dy_{0.4}$) were prepared into rod shapes by both Bridgman and free-standing zone-melting (FSZ) techniques.[5] Magnetization measurements were made on disk samples but normal to the growth direction in fields up to 800 kA/m using a commercial vibrating sample magnetometer. Young's moduli were measured by two methods. In the first method, static stress-strain curves were taken on rod samples (~3 cm × 0.3 cm diam.) at room temperature in the absence of a magnetic field. The strain was measured by multiple strain gauges affixed to the sample and the stress was measured using a conventional load cell. In order to determine the extent of the magnetomechanical hysteresis, measurements were taken by applying both increasing and decreasing stresses. For the $R_{0.42}Fe_{0.58}$ alloy and for the RFe_2 compound, Young's moduli were also measured as a function of magnetic field up to 160 kA/m at fixed compressive stresses of ~15 MPa at room temperature and 77 K using standard strain-gauge techniques. These moduli were measured under the two limiting magnetic conditions of (1) fixed magnetic field and (2) fixed magnetic induction. Magnetostriction measurements were made in fields up to 160 kA/m at room temperature and 77 K using strain-gauge and LVDT techniques. Magnetization measurements were made concurrently by integrating the voltage of a pickup coil wound around the samples.

In all samples, the magnetization process consists of two regions: (1) a region of nonmagnetostrictive 180° wall motion, resulting in a rapid rise in magnetization at low fields; and (2) a magnetostrictive noncollinear wall motion and magnetization rotation region resulting in a smaller magnetization change and approach to saturation. The magnetization curves of Fig. 1 reflect this process. At room temperature, only the RFe_2 component of the alloy is magnetic. Thus, as the weakly paramagnetic $Tb_{0.6}Dy_{0.4}$ alloy is added to RFe_2 to form the eutectic samples, the magnetization decreases. The coercive force is largest for the $R_{0.72}Fe_{0.28}$ sample. At 77 K the rare-earth component R has the larger magnetic moment. Therefore, as expected, as R is added to RFe_2, the magnetization increases. Again a maximum in the

coercive force is observed for the eutectic composition $R_{0.72}Fe_{0.28}$.

Because of the very large uniaxial anisotropy in the hexagonal rare earths Tb and Dy, the polycrystalline R and alloys containing R are difficult to saturate at low temperatures. The magnetization versus temperature curves for these alloys are shown in Fig. 2. The full magnetic moment of the R component is not reached at 800 kA/m. As expected, a large increase in magnetization below 200 K occurs as the R component becomes ordered. The change in the slope of the curves, even of the $R_{0.42}Fe_{0.58}$ sample, which contains only 14% R, is clearly detected. A striking feature of the magnetization versus temperature curve is the appearance of a peak in the magnetization of $T \cong 210$ K for small applied fields. It is well known that a basal plane spiral magnetization structure exists in the Tb_xDy_{1-x} alloy system.[6] We observe that the coexistence of the RFe_2 component in the eutectic does not significantly alter T_N. Thus, the spiral structure of $Tb_{0.6}Dy_{0.4}$ remains essentially unchanged in the eutectic structure, and we conclude that the contributions to the magnetization from the individual R and RFe_2 phases within the eutectic are simply additive.

For most applications utilizing magnetostrictive materials, it is important to know the mechanical stiffness. We report measurements of Young's moduli at room temperature and at 77 K. In Fig. 3 we illustrate the stress-strain relationships at room temperature for the Bridgman-prepared samples in the absence of an applied magnetic field. The addition of the R component to the RFe_2 compound consists of two major features: (1) a reduction of the stiffness with the addition of the softer rare-earth binary alloy; and (2) a large magnetically induced hysteresis in the RFe_2 and the eutectic containing alloy richest in RFe_2. In these two cases, the moduli strongly depend upon the magnetic history of the sample. For RFe_2 and $R_{0.42}Fe_{0.58}$, Young's moduli measurements were taken with the samples premagnetized parallel to the rod axis to achieve the maximum magnetic moment rotation in an applied magnetic field. As the compressive stress is applied to these samples, the magnetization in the domains rotates from parallel to perpendicular to the rod axis, yielding a softening of the sample and the well-known ΔE effect. As the magnetic moments become nearly perpendicular to the rod axis ($\sigma > 60$ MPa), both samples become significantly harder. The fraction of RFe_2 is small in the samples richer in R and the hysteresis becomes negligible. The pure eutectic $R_{0.72}Fe_{0.28}$ alloy and those richer in R are also more ductile and deform under stresses greater than ~100 MPa. Young's moduli, calculated from the high-stress slopes of Fig. 3, are 110, 83, 77, and 72 GPa for RFe_2, $R_{0.42}Fe_{0.58}$, $R_{0.72}Fe_{0.28}$, and $R_{0.9}Fe_{0.1}$, respectively.

The effect of magnetic field on the moduli is shown in Fig. 4 for RFe_2 and $R_{0.42}Fe_{0.58}$ at room temperature and 77 K ($\sigma \cong 15$ MPa). When an axial magnetic field is applied to a positive magnetostriction material under a preexisting compressive stress, the magnetic moments again rotate, but now from perpendicular to parallel to the rod axis. As this rotation process takes place in the applied magnetic field, the elastic moduli at first decreases and then increases as the rotation process becomes complete. For the RFe_2 compound, the

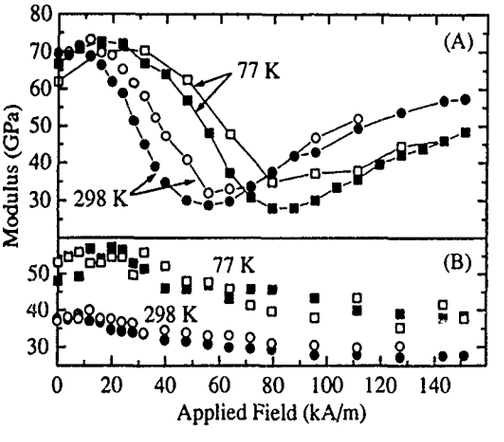

FIG. 4. Modulus under constant-field conditions Y^H and under constant induction Y^B vs applied field for Bridgman-prepared samples: (A) $(Tb_{0.6}Dy_{0.4})_{0.33}Fe_{0.67}$ at 15.8 MPa and (B) $(Tb_{0.6}Dy_{0.4})_{0.42}Fe_{0.58}$ at 15.4 MPa [(□) Y^B at 77 K, (■) Y^H at 77 K, (○) Y^B at 298 K, and (●) Y^H at 298 K]

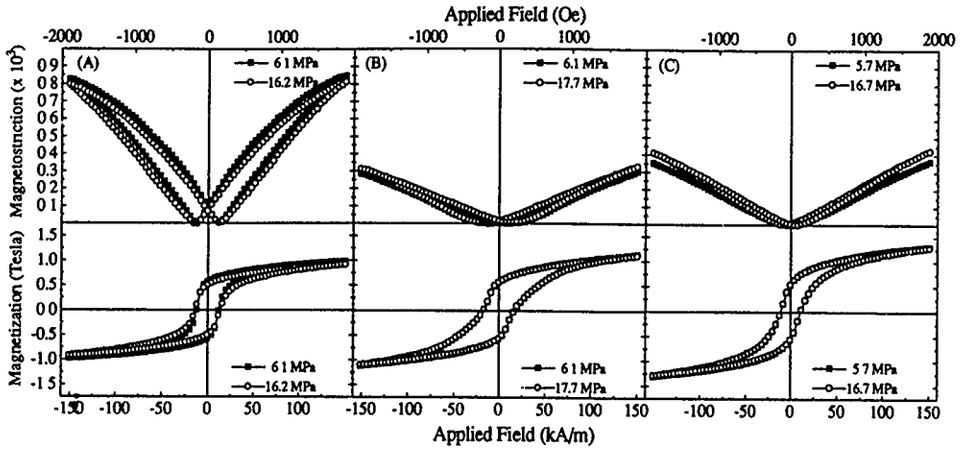

FIG. 5. Field dependencies of the magnetization and magnetostrictions for Bridgman-prepared samples: (A) $(Tb_{0.6}Dy_{0.4})_{0.42}Fe_{0.58}$; (B) $(Tb_{0.6}Dy_{0.4})_{0.72}Fe_{0.28}$, and (C) $(Tb_{0.6}Dy_{0.4})_{0.9}Fe_{0.1}$ at two compressive stresses.

easiest rotation takes place near 85 kA/m at 77 K (55 kA/m for room temperature). For the sample containing the smallest amount of eutectic, $R_{0.42}Fe_{0.58}$, the easiest rotation process occurs at a field higher than 160 kA/m. To evaluate the effect of 180° domain-wall motion in creating the nonmagnetostrictive magnetization process, measurements were taken under both constant magnetic field H and constant magnetic induction B. In these samples, both Y^B and Y^H decrease with applied field. Thus, even when the total induction is kept fixed, the domains redistribute themselves in such a way that yields some magnetization rotation and magnetostriction. Thus, the accepted conventional relationship between the coupling factor and Young's moduli, $k^2=1-Y^H/Y^B$, is not valid here.

At room temperature the magnetization and magnetostriction decrease rapidly with the addition of R to the RFe_2 compound. In this section we report the magnetization and magnetostriction at 77 K in magnetic fields up to 160 kA/m. Figure 5 illustrates the field dependencies for the $R_{0.42}Fe_{0.58}$, $R_{0.28}Fe_{0.72}$, and $R_{0.9}Fe_{0.1}$ alloys at compressive stresses σ of ~6 and ~17 MPa for the Bridgman-prepared samples. Similar results are observed for the FSZ samples, but not reported here. The expected σ dependencies of the magnetization and magnetostriction, characteristic of both R and the RFe_2 compound, are not seen. Here, little or no stress dependence was observed. Also striking is the large reduction in the magnetostriction with the addition of a small amount of the R component to the RFe_2 compound. In the RFe_2 compound (not shown), the magnetostriction reaches 2200×10^{-6} at 160 kA/m. As observed in Fig. 5(a), the magnetostriction of $R_{0.42}Fe_{0.58}$ is only $\sim800\times10^{-6}$. With samples richer in R, the magnetostriction decreases still further, even though the magnetostriction of the R is much higher than that of RFe_2. These unexpectedly low magnetostriction values are shown in Figs. 5(b) and 5(c) along with their corresponding magnetizations. Note the hysteresis is largest for the pure eutectic, $R_{0.72}Fe_{0.28}$. The conclusion reached is that the high c-axis texture of the rod samples, with the large uniaxial anisotropy, inhibits the large magnetization rotations required for giant magnetostrictions. In the R-rich samples, the magnetostrictions reach only $\sim400\times10^{-6}$, compared with the huge $\sim6000\times10^{-6}$ previously reported for the basal plane oriented $Tb_{0.6}Dy_{0.4}$ single crystals.[1]

The Néel and Curie temperatures of R ($=Tb_{0.6}Dy_{0.4}$) were clearly observed in all of the eutectic-containing alloys. Thus, the presence of RFe_2 component in the eutectic does not noticeably affect the magnetic properties of the R component, even its magnetic structure. On the other hand, the giant magnetostriction of the R component of the eutectic was not realized. Because of the highly textured nature of the Bridgman and FSZ samples and a strong R uniaxial anisotropy, the magnetostriction (for $H<160$ kA/m) is found to decrease as the portion of the highly magnetostrictive R component of the alloy is increased. Finally, Young's modulus decreases as the R/RFe_2 ratio in R_xFe_{1-x} ($0.33\leq x\leq1$) increases. The modulus in the $R_{0.42}Fe_{0.58}$ alloy is highly hysteretic and does not exhibit the large ΔE effect of the single-phase RFe_2 compound.

Research on magnetostrictive intermetallic alloys at the Naval Surface Warfare Center is sponsored by the Navy Independent Research Program.

Theory of magnetostriction with application to Terfenol-D

R. D. James

D. Kinderlehrer
Center for Nonlinear Analysis and Department of Mathematics, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213

A mechanism for magnetostriction in the highly magnetostrictive material Terfenol-D is explained in detail. This mechanism is based on a theory of magnetostriction [R. D. James and D. Kinderlehrer, Philos. Mag. B **68**, 237 (1993)] that is particularly suited to predictions of the macroscopic behavior of materials that exhibit large magnetostriction. Some experiments that test these predictions are proposed.

I. INTRODUCTION

A theory of magnetostriction that is adapted to the description of large magnetostriction is given by the authors in Ref. 1. The theory is a micromagnetic in nature and follows the pattern established by Brown.[2] The focus is on an exact specification of the potential wells of the anisotropy energy.

For large specimens such as those encountered in usual actuator applications, the presence of complicated domain structures has hindered the usefulness of micromagnetic theories that seek to incorporate magnetostriction. In recent years new methods of calculating energy minimizers for this situation have emerged, partly as a result of advances in the analysis of the microstructure of martensite and partly as a result of related developments on the design of optimal composites. Using these ideas, the authors[1] found compatible energy minimizing domain structures for the theory specialized to a growth-twinned specimen of $Tb_xDy_{1-x}Fe_2$, $x \approx 0.3$ (Terfenol-D).

The patterns found in Ref. 1 consist of laminates which meet at the growth twin boundary; see, e.g., Fig. 1. Each layer of the laminate has a constant deformation gradient and a substructure of magnetic domains. The motivation for looking at laminates as energy minimizers arose from the observations of Lord *et al.*[3] Analyzing all possible compatible energy-minimizing laminates that meet at the growth twin boundary, we found five distinct energy minimizing microstructures, pictured in Fig. 1, one of which agreed with the photomicrograph of Lord *et al.* Subsequently, all of the other four patterns were observed (Lord[4]), with good agreement of the geometry and even (in the cases available) of the magnetic substructure.

Each of these structures is kinematically compatible and energy minimizing for all values of the volume fraction γ. As γ changes from 0 to 1 the sample experiences a macroscopic strain in the direction $[-211]$, the typical axial direction of a Terfenol-D rod; however, the amount of strain differs for the different laminates. It might then be inferred that, after a few cycles, the rod would be likely to choose the domain structure that yields the maximum magnetostrictive strain, because there is certainly an energy barrier to changing the whole pattern.

A more refined prediction suggests that something different might occur. There are actually two kinds of laminated microstructures predicted by the theory. In the first kind, analogous to "semicoherent" interfaces in the literature on martensite, the laminates are separated by a transition layer, which of course contains some energy. The value of this energy is proportional to the twin spacing, so it can be reduced as close to zero as desired by refining the twins. The second kind of laminate has no transition layer; it is "exactly compatible." The property of being exactly compatible versus approximately compatible is predicted by the theory; it is not just based on microscopic examination. With exchange energy present, it is clear that exactly compatible laminates are energetically preferred over those which have a transition layer.

Exactly compatible laminates have another interesting feature: The volume fraction γ can change with position along the growth twin boundary, giving them some additional freedom to meet remote conditions.

When we went back and checked the different laminates, we found that the laminate which achieves maximum magnetostrictive strain is not exactly compatible. This suggests that there may possibly be a drastic change in the domain pattern, and as explained herein, this would be favored by compressive stress. These predictions are explained in more detail below. They suggest some interesting experiments, now in progress (Tickle[5]).

These considerations apply to a specimen with parallel growth twins, such as one that is obtained by float-zone processing. Bridgman-grown specimens contain a significant number of grain boundaries and sometimes several different growth twin systems, which surely would rule out simple laminated energy minimizers.

II. THEORY OF TERFENOL-D

We give a brief description of the theory specialized to Terfenol-D. The basic unknown functions of the theory are the deformation $\mathbf{y}(\mathbf{x})$ and magnetization $\mathbf{m}(\mathbf{y})$. These are minimizers or relative minimizers of the total free energy

$$E(\mathbf{y},\mathbf{m}) = \int_\Omega \varphi\{\nabla \mathbf{y}(\mathbf{x}), \mathbf{m}[\mathbf{y}(\mathbf{x})]\} d\mathbf{x} + \tfrac{1}{2}\int_{R^3} |\nabla u(\mathbf{z})|^2 \, d\mathbf{z}. \tag{1}$$

Here Ω is the reference configuration of the specimen, φ is the anisotropy energy, and the magnetostatic potential u is determined from $\mathbf{m}$ by solving the magnetostatic equation

$$\operatorname{div}(-\nabla u + \mathbf{m}) = 0 \quad \text{on } R^3. \tag{2}$$

In solving this equation it is understood that $\mathbf{m}=0$ outside of $\mathbf{y}(\Omega)$, the deformed configuration. The theory is geometri-

 0021-8979/94/76(10)/7012/3/$6.00 © 1994 American Institute of Physics

cally exact, to allow it to apply for arbitrarily large deformations. In fact, the elasticity could be linearized. and then the theory would be similar to that of Clark,[6] but it is no more difficult to calculate the energy minimizers for the geometrically exact theory. The energy (1) is appropriate to a single-crystal specimen. Supposing that Ω is divided in two by a growth twin on the plane $\mathbf{x}\cdot\mathbf{m}_1=0$, so that $\Omega=\Omega_1\cup\Omega_2$ with $\Omega_1=\Omega\cap(\mathbf{x}\cdot\mathbf{m}_1>0)$ and $\Omega_2=\Omega\cap(\mathbf{x}\cdot\mathbf{m}_1<0)$, then the appropriate expression for the energy is

$$E_{gt}(\mathbf{y},\mathbf{m})=\int_{\Omega_1}\varphi\{\nabla\mathbf{y}(\mathbf{x}),\mathbf{m}[\mathbf{y}(\mathbf{x})]\}d\mathbf{x}+\int_{\Omega_2}\varphi\{\nabla\mathbf{y}(\mathbf{x})\mathbf{R}_0,\mathbf{m}[\mathbf{y}(\mathbf{x})]\}d\mathbf{x}+\frac{1}{2}\int_{R^3}|\nabla u(\mathbf{z})|^2\,d\mathbf{z}, \tag{3}$$

where $\mathbf{R}_0$ is a 180° rotation about $\mathbf{m}_1$. Here $\mathbf{m}_1$ is proportional to (111) and expression (3) takes into account the observed crystallography of the type-I growth twins of Terfenol-D. When minimizing Eq. (3), compatibility at the growth twin boundary is automatically taken into account by the assumption that $\mathbf{y}(\mathbf{x})$ is continuous on Ω. Finally, expressions (2) and (3) are appropriate for no applied field or loads.

The key feature about the anisotropy energy φ is its potential-well structure. For Terfenol-D it is assumed to have minima on the set

$$\{\mathbf{RU}_1,\pm\mathbf{Rm}_1\}\cup\{\mathbf{RU}_2,\pm\mathbf{Rm}_2\}$$
$$\{\mathbf{RU}_3,\pm\mathbf{Rm}_3\}\cup(\mathbf{RU}_4,\pm\mathbf{Rm}_4\}, \tag{4}$$

where $\mathbf{m}_1=\alpha[111]$, $\mathbf{m}_2=\alpha[-111]$, $\mathbf{m}_3=\alpha[1-11]$, $\mathbf{m}_4=\alpha[11-1]$, $\mathbf{U}_i=\eta_1\mathbf{1}+(\eta_2-\eta_1)\hat{\mathbf{m}}_i\otimes\hat{\mathbf{m}}_i$, $\hat{\mathbf{m}}_i=\mathbf{m}_i/|\mathbf{m}_i|$, $i=1,\ldots,4$, and $\mathbf{R}$ is an arbitrary proper 3×3 rotation matrix. The scalar constant of proportionality α is $1/\sqrt{3}$ of the saturation magnetization, η_2-1 is the saturation strain along [111], and η_1-1 is the saturation strain along $[1-10]$. The notation $\mathbf{a}\otimes\mathbf{b}$ denotes the matrix with components a_ib_j and $\mathbf{1}$ is the identity matrix. Thus, the linear transformation $\mathbf{U}_1$ transforms a cube (aligned with the cubic axes in Ω) by stretching its [111] diagonal with a strain η_2-1 while contracting every direction perpendicular to [111] with a strain η_1-1. This can be seen by applying $\mathbf{U}_1$ to unit vectors in the various directions. We shall say that the specimen is in variant i at a point $\mathbf{x}\in\Omega_1$ if $[\nabla\mathbf{y}(\mathbf{x}),\mathbf{m}(\mathbf{x})]$ has the form $\{\mathbf{QU}_i,\pm\mathbf{Qm}_i\}$ for some rotation matrix $\mathbf{Q}$. A different notation is appropriate for the region Ω_2; that is, because of the presence of $\mathbf{R}_0$ in Eq. (3), the potential wells are modified there. Hence, we say that the specimen is in variant i' at a point $\mathbf{x}\in\Omega_2$ if $[\nabla\mathbf{y}(\mathbf{x}),\mathbf{m}(\mathbf{x})]$ has the form $\{\mathbf{QR}_0\mathbf{U}_i\mathbf{R}_0,\pm\mathbf{QR}_0\mathbf{m}_i\}$ for some rotation matrix $\mathbf{Q}$.

III. ENERGY-MINIMIZING COMPATIBLE DOMAIN STRUCTURES

The energy minimizers computed in Ref. 1 consist of laminates above and below the growth twin boundary. All possible compatible laminates were considered; that is, it was assumed that $\nabla\mathbf{y}$ oscillated between two values on Ω_1 and two different values on Ω_2, with possibly a transition layer in between. To be energy minimizing, these values necessarily have to come from the potential wells (4), the energy in the transition layer has to be reducible to zero by refining the layers, and the substructure of magnetic domains has to be arranged to make the field energy arbitrarily small (see Ref. 1 for the details of how this was done).

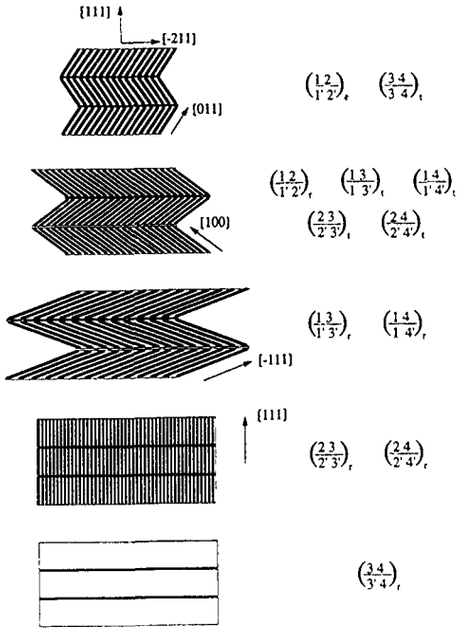

FIG 1 Appearance of the predicted laminates on the (0-11) plane with light and dark denoting the individual layers within a laminate. The magnetic substructure is not shown.

To summarize the results of these calculations, we use the notation

$$\left\langle\frac{ij}{k'l'}\right\rangle_{\text{subscript}} \tag{5}$$

to denote a minimizer which uses variants i and j on Ω_1 and k' and l' on Ω_2. The subscript can take the value t ("twin") or r ("reciprocal twin") which refers to which of the two kinematically compatible interfaces ({100} or {110}, respectively) is used in making the laminate; this choice also affects the rotations involved. Using this notation, all compatible variants are shown in Fig. 1. This figure shows only the domains of distortion [as would be revealed by differential interference contrast (DIC) microscopy, for example], not the magnetic substructure. Energy minimization gives one additional restriction: The volume fraction above and below the growth twin boundary is necessarily the same.

As mentioned in Sec. I, some of these laminates are exactly compatible. Exact compatibility is most easily explained by Fig. 2. An approximately compatible laminate has the property that the energy in the transition layer can be reduced to zero by refining the layers. Exchange energy imposes a limit to how much the laminates can be refined, and the ultimate fineness is determined by a compromise between the energy in the transition layer and the total interfacial energy. Exactly compatible laminates have no transition layer and, therefore, can be coarse or fine, and the tendency would be toward coarseness since the only energy present is exchange.

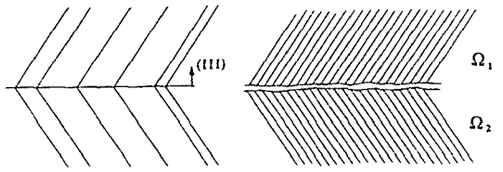

FIG. 2 Exactly compatible configuration (left-hand side) and approximately compatible configuration (right-hand side) laminates.

The exactly compatible laminates are[1]

$$\frac{23}{3'3'} \quad \frac{34}{3'4'} \quad \frac{24}{2'4'}. \tag{6}$$

IV. MECHANISM OF MAGNETOSTRICTION

If we imagine a unit line segment drawn on the specimen in the $[-211]$ direction above the Curie point (i.e., in the reference configuration), this line will become a zig-zag line when evaluated for any of these laminates. It will never "break," as we have assumed kinematic compatibility [i.e., the continuity of $\mathbf{y}(\mathbf{x})$]. For such a line that is long compared to the layer width, the length of the line depends only on the volume fraction γ and the choice of the laminate. A line in the $[-211]$ direction will have the same length whether it is placed above or below the growth twin boundary, by compatibility. It is easy to calculate the maximum and minimum lengths of such lines, as γ goes from 0 to 1, for all the laminates, and the result is given in Table I. (The right-hand-side column is an evaluation of these lengths for material constants η_1 and η_2 appropriate for Terfenol-D, obtained by using surface relief measurements of Al-Jiboory and Lord.[7]) It is seen from Table I that the maximum strain $\Delta l/l$ is obtained using the variants 1 2; however, from Eq. (6) these variants do not achieve exact compatibility. Another look at Table I shows that the reason that the variants 1 2 give the maximum magnetostrictive strain is that they give both the shortest (0.9992) and the longest (1.001 33) length; but, in fact, the variant pairs 2 3 and 2 4, both of which are exactly compatible, have the same maximal length (1.001 33) as 1 2 but their minimum length is longer.

TABLE I. The minimum and maximum macroscopic lengths of a line oriented along $[-211]$ which in the reference configuration had unit length.

Variants	Length	Length with $\eta_1=0.9992$, $\eta_2=1.0016$
1 2	$\min \eta_1$	0.9992
	$\max[\eta_1^2+\frac{8}{9}(\eta_2^2-\eta_1^2)]^{1/2}$	1 001 33
1 3	$\min \eta_1$	0.9992
	$\max[\eta_1^2+\frac{2}{9}(\eta_2^2-\eta_1^2)]^{1/2}$	0.999 73
1 4	$\min \eta_1$	0.9992
	$\max[\eta_1^2+\frac{2}{9}(\eta_2^2-\eta_1^2)]^{1/2}$	0 999 73
2 3	$\min[\eta_1^2+\frac{2}{9}(\eta_2^2-\eta_1^2)]^{1/2}$	0 9997
	$\max[\eta_1^2+\frac{8}{9}(\eta_2^2-\eta_1^2)]^{1/2}$	1 001 33
3 4	$\min\left(\eta_1^2+\frac{2}{9}(\eta_2^2-\eta_1^2)-\frac{(\eta_1^2-\eta_2^2)^2}{3(2\eta_2^2+\eta_1^2)}\right)^{1/2}$	0 999 47
	$\max[\eta_1^2+\frac{2}{9}(\eta_2^2-\eta_1^2)]^{1/2}$	0 999 73
(3 4),	$\min=\max=[\eta_1^2+\frac{2}{9}(\eta_2^2-\eta_1^2)]^{1/2}$	0.999 73
2 4	$\min[\eta_1^2+\frac{2}{9}(\eta_2^2-\eta_1^2)]^{1/2}$	0.999 73
	$\max[\eta_1^2+\frac{8}{9}(\eta_2^2-\eta_1^2)]^{1/2}$	1 001 33

Computations with applied field and load using the present theory are in progress,[8] but are not yet available; however, as far as the effect of small or moderate loads and fields is concerned, it is likely that they will reveal that compressive stress will favor variants yielding the shortest length, while applied fields in the direction $[-211]$ will favor variants yielding the longest length (This comes from a closer examination of the magnetic subdomain structure.)

Putting these assumptions together with the idea that exactly compatible variants are preferred, we can arrive at a proposal for what might happen. With no compressive stress or applied field, variants 2 3, 2 4, or perhaps 3 4 would be preferred. Still in the absence of stress but with a $[-211]$ field applied, 2 3 and 2 4 are then preferred, even up to large fields, because they give maximum extension and they are exactly compatible; however, upon application of compressive stress, there is clearly a preference for 1 2 (or 1 3 or 1 4, which, however, would not seem to survive cycling the stress, because they achieve only modest maximal lengths).

V. PROPOSED EXPERIMENTS

This proposal suggests some relatively simple experiments. Since the domains of distortion discussed above are observed by making use of surface relief, it is important to polish the specimen in the single-domain state. Failure to do this will result in the possibility of seeing false domain boundaries at places where leveled domain boundaries existed during polishing. Since it is difficult to polish above the Curie temperature, it is reasonable to use stress to do this. According to the results of the theory, a compressive stress favors the single-domain state consisting of variant 1, and a reasonably large compressive stress is advised, to overcome barriers associated with the inevitable defects. A fixture has been built to do this.

With domains of distortion revealed, the experiment consists of observing the effects of applied field and compressive stress on the domain pattern and macroscopic magnetostriction, as indicated in the last paragraph of Sec. IV. The switch from variants 2 3 to 1 2 should be accompanied by a significant change of both the geometry and the fineness.

Recent developments in modeling of the stress derivative of magnetization in ferromagnetic materials

D. C. Jiles and M. K. Devine
Ames Laboratory, Iowa State University, Ames, Iowa 50011

The effect of changing stress on the magnetization of ferromagnetic materials leads to behavior in which the magnetization may increase, or decrease, when exposed to the same stress under the same external conditions. A simple empirical law seems to govern the behavior when the magnetization begins from a major hysteresis loop. The application of the law of approach, in which the derivative of the magnetization with respect to the elastic energy supplied dM/dW is proportional to the magnetization displacement $M_{an}-M$, is discussed.

Previous work on the development of model theories of the magnetization processes in ferromagnetic materials have concentrated on the description of hysteresis[1,2] and the changes in hysteresis curves which result from constant applied stress.[3–5] The magnetomechanical effect, which is defined as the change in magnetization of a magnetic material resulting from a changing applied stress under a constant applied field, has been reported occasionally,[6,7] but the effects have appeared to be very complex. For example, in the closely related works of Craik and Wood[8] and of Birss, Faunce, and Isaac,[9] the experimental results were obtained by applying different stresses to various polycrystalline magnetic materials in the presence of a small constant magnetic field. As noted by Craik and Wood, there were many features in the results which cannot be reconciled with the previous theory of Brown.[10]

Birss,[11] Schneider and Charlesworth,[12] and Finbow[13] have mentioned the prediction of Brown's theory that the changes in magnetization should be independent of the sign of the stress (i.e., symmetric with stress), which is contrary to the experimental results presented in these articles. The "wall pressure" theory developed by Brown, and later by Brugel and Rimet,[14] predicts that the magnetization remains constant as the stress is reduced from its maximum amplitude. This was termed the "horizontal fly-back" by Birss and co-workers,[9] which is known to be at variance with experimental observations, as shown by Schneider and Richardson[15] and Schneider and Semcken,[16] as well as in the results of Craik and Wood,[8] Birss and co-workers,[9] and Jiles and Atherton.[17]

Following the observation by Bozorth and Williams[6] that the magnetization curve of Permalloy 68, obtained after application of a magnetic field followed by stress of 39 MPa (4 kg mm^{-2}), was "as closely as it was possible to tell, identical to the anhysteretic magnetization curve," it was suggested[17] that the main effect of stress cycling on the magnetization causes it to approach the anhysteretic.

The concept of the law of approach was tested by Pitman[18] and later by Maylin and Squire.[19] The results, according to Pitman, seemed to confirm the law of approach, with the results from positive and negative remanence being mirror images of each other, while the amplitude of the change in magnetization was found to be much reduced when the point on the initial magnetization curve was close to the demagnetized state.

The results Maylin and Squire substantiated these results for locations beginning from the major loop; however, for locations beginning on a minor (i.e., asymmetric) loop, the law of approach, if it was operative, did not seem to pertain to the principal anhysteretic magnetization.

There are probably three factors which determine the magnitude and sign of the magnetomechanical effect: (i) how far the prevailing magnetization is above or below the anhysteretic (the displacement): (ii) how sensitive this displacement is to stress (the rate of decay); and (iii) how the anhysteretic changes with stress.

As described in previous work,[3] an applied uniaxial stress acts on a multidomain polycrystalline material like an applied magnetic field operating through the magnetostriction, and this additional "effective field" can be described by

$$H_\sigma=\frac{3}{2}\frac{\sigma}{\mu_0}\left(\frac{d\lambda}{dM}\right)_\sigma. \tag{1}$$

Therefore, if the magnetostriction λ can be described as a function of magnetization and stress, the anhysteretic magnetization at field H and stress σ becomes identical to the anhysteretic at field $H+H_\sigma$ and zero stress,

$$M_{an}(H,\sigma)=M_{an}(H+H_\sigma,0)=M_{an}\left[H+\frac{3}{2}\frac{\sigma}{\mu_0}\left(\frac{d\lambda}{dM}\right)_\sigma,0\right], \tag{2}$$

where the effects of stress have been incorporated into the effective field. A reasonable first approximation to the magnetostriction of iron can be obtained by using the series expansion

$$\lambda=\sum_{i=1}^{\infty}\gamma_i M^{2i}, \tag{3}$$

which enables the derivative $d\lambda/dM$ to be calculated.

The stress dependence of the magnetostriction curve $\lambda(M,\sigma)$ can be described from the stress dependence of the coefficients γ_i. Using a Taylor series expansion,

$$\gamma_i(\sigma)=\gamma_i(0)+\sum_{n=1}^{\infty}\frac{\sigma^n}{n!}\gamma_i^n(0), \tag{4}$$

where $\gamma_i^n(0)$ is the nth derivative of γ_i with respect to stress at $\sigma=0$.

The stress dependence of the anhysteretic magnetization curve can be determined from

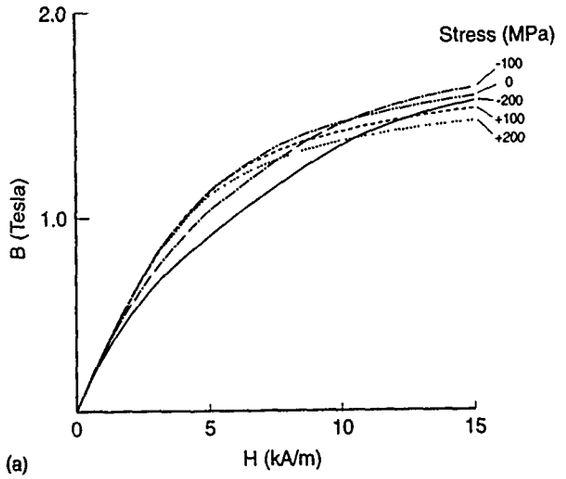

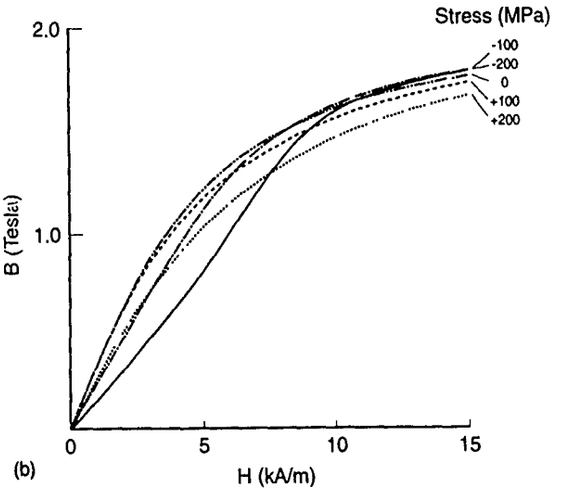

FIG. 1. (a) Measured variation of the anhysteretic magnetization with stress, as reported by Jiles and Atherton (Ref. 17); (b) modeled variation of the anhysteretic magnetization curve for various levels of stress together with the following values of the coefficients: $M_s=1.7\times10^6$ A/m, $a=100$ A/m, $k=1000$ A/m, $\alpha=0.001$, $c=0.1$, $\gamma_1=4\times10^{-18}-(3\times10^{-26})\sigma$ A^{-2} m^2, and $\gamma_2=2\times10^{-30}-(5\times10^{-39})\sigma$ A^{-4} m^4.

$$M_{an}(H,\sigma)=M_s\left[\coth\left(\frac{H+H_\sigma+\alpha M}{a}\right)-\frac{a}{H+H_\sigma+\alpha M}\right]. \tag{5}$$

The predictions of the present mode equation for the stress dependent anhysteretic are shown in Fig. 1 for selected values of the model parameters. It is clear from these results that there is good agreement with the experimental results of Jiles and Atherton.

The magnetization may increase or decrease when exposed to the same stress under the same external conditions. This indicates that the phenomenon is dependent on more than simply the external effects of stress and field. In fact the behavior depends on the magnetization history of the specimen.

We have now two factors to consider: the displacement from the anhysteretic and the change in elastic energy. The proposition which we wish to test is that the derivative of the magnetization with the change in elastic energy supplied W obeys a law of approach,

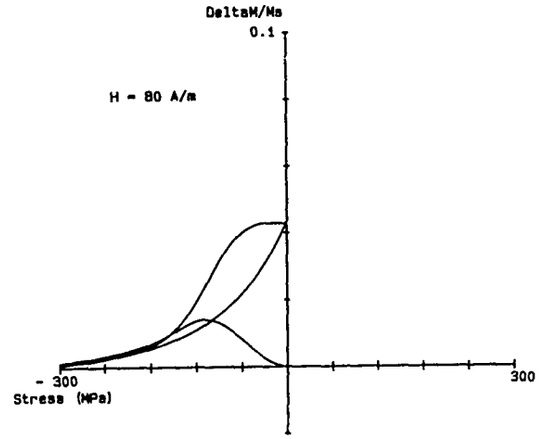

FIG. 2. Variation of magnetization with applied stress at a field strength of 80 A m^{-1} close to the anhysteretic magnetization curve and slightly below it. The right-hand-side half of the diagram shows the behavior in tension and the left-hand-side half shows the behavior in compression. The values of the quantities used were: $\epsilon=100\times10^6$ Pa, $\gamma_1=4\times10^{-18}-(3\times10^{-26})\sigma$ A^{-2} m^2, and $\gamma_2=2\times10^{-30}-(5\times10^{-39})\sigma$ A^{-4} m^4.

$$\frac{dM}{dW}=\frac{1}{\xi}(M_{an}-M), \tag{6}$$

where now ξ is a decay coefficient which has units of J m^{-3}. The change in elastic energy supplied to the material when the stress is changed from σ_0 to σ is

$$W=\frac{1}{E}(\sigma-\sigma_0)^2, \tag{7}$$

where E is the elastic modulus. Therefore, substituting

$$dW=\frac{2}{E}(\sigma-\sigma_0)d\sigma \tag{8}$$

into Eq. (6) gives

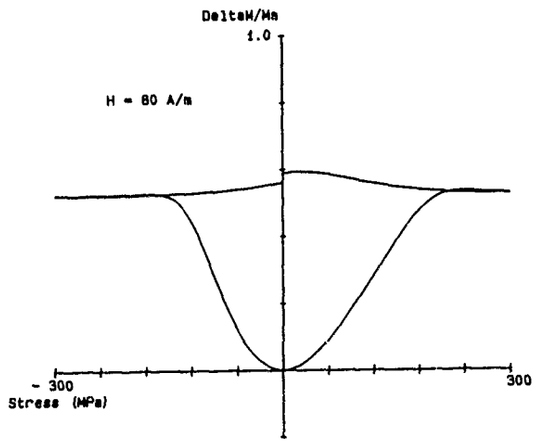

FIG. 3. Variation of magnetization with stress at 80 A m^{-1} along the lower loop of the magnetization curve after reducing from a field amplitude of -5000 A m^{-1}. The values of the quantities used were. $\epsilon=100\times10^6$ Pa, $\gamma_1=4\times10^{-18}-(3\times10^{-26})\sigma$ A^{-2} m^2, and $\gamma_2=2\times10^{-30}-(5\times10^{-39})\sigma$ A^{-4} m^4.

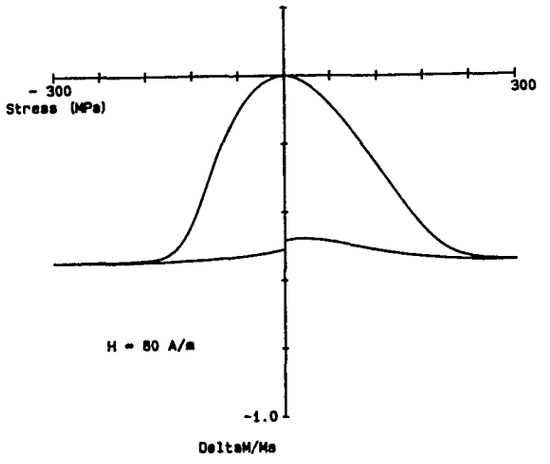

FIG. 4. Variation of magnetization with stress at 80 A m^{-1} along the upper loop of the magnetization curve after reducing from a field amplitude of 5000 A m^{-1}. The values of the quantities used were: $\epsilon=100\times10^6$ Pa, $\gamma_1=4\times10^{-18}-(3\times10^{-26})\sigma$ $A^{-2}m^2$, and $\gamma_2=2\times10^{-30}-(5\times10^{-39})\sigma$ $A^{-4}m^4$.

$$dM=\frac{2}{\epsilon^2}(\sigma-\sigma_0)(M_{an}-M)d\sigma, \tag{9}$$

where $\epsilon^2=E\xi$, and ϵ has units of Pa.

Rearranging Eq. (9) and integrating,

$$\int \frac{dM}{M-M_{an}}=-\frac{2}{\epsilon^2}\int(\sigma-\sigma_0)d\sigma, \tag{10}$$

and consequently

$$M_{an}-M(\sigma)=[M_{an}-M(\sigma_0)]\exp\left[-\left(\frac{\sigma-\sigma_0}{\epsilon}\right)^2\right], \tag{11}$$

which, on subtraction from $M_{an}-M(\sigma_0)$, gives the change in magnetization ΔM,

$$\Delta M=M(\sigma)-M(\sigma_0)$$
$$=[M_{an}-M(\sigma_0)]\left\{1-\exp\left[-\left(\frac{\Delta\sigma}{\epsilon}\right)^2\right]\right\}, \tag{12}$$

where $\Delta\sigma=\sigma-\sigma_0$. This gives the symmetric dependence of magnetization on stress.

However, if M_{an} is stress dependent, as is generally the case, then this stress dependence needs to be incorporated, as shown in Eq. (2), which leads to a more complicated integration. In practice, it has been found best under all conditions to simply evaluate Eq. (9) numerically using computer techniques.

Experimental results of Pitman[18] exhibit the principal feature of interest, which is the ΔM vs $\Delta\sigma$ locus under compression (first an increase, and at higher compressive stress a decrease in M, under conditions close to, but slightly below, the anhysteretic). Then positive, or negative, changes in M with the same compressive stress, and under the same applied field, depending on whether the magnetization began well below, or well above, the anhysteretic.

The results of Craik and Wood[8] were more diverse than those of Pitman, and in particular their results showed the essential asymmetry of the magnetization versus stress curves at higher stress levels. At small stress amplitudes of up to about ±0.5 kg mm^{-2} ($=4.9\times10^6$ Pa), the change in magnetization with stress was almost symmetric. Even up to ±2 kg mm^{-2} (19.6×10^6 Pa), the sign of the change was positive under both tension and compression; but, beyond ±3 kg mm^{-2} (29.4×10^6 Pa), the change of magnetization with stress was negative under compression but positive under tension. A wide range of different behaviors of magnetization under stress was reported by Craik and Wood, showing asymmetry under tension or compression, and in which the amplitude of the changes was dependent on the strength of the constant applied magnetic field; however, because Craik and Wood did not measure the anhysteretic magnetization, the physical significance of the observed changes was not clear from their work.

In the work of Birss[11] it was found that for small changes in magnetization the magnetization versus stress curves were symmetric with respect to stress. For larger changes in magnetization, Birss reported similar findings to Craik and Wood: namely, a change in sign of the stress derivative under compression, leading to an asymmetric behavior.

The results of model calculations are shown in Figs. 2–4. It can be seen from the results of Fig. 2 at a field strength of 80 A/m that the slope of the curve of ΔM vs $\Delta\sigma$ changes sign in the compressive region at about -100 MPa. This result is similar in behavior to the data of Craik and Wood,[8] Birss and co-workers,[9] and Pitman.[18] The results in Figs. 3 and 4 show that the change in magnetization is positive or negative, depending on whether the initial magnetization state is below or above the anhysteretic, respectively. The resultant curves here are in excellent agreement with the reported results of Pitman.[18]

Magnetization and magnetostriction curves from micromagnetics

Antonio DeSimone[a)]
Center for Nonlinear Analysis, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213

The macroscopic behavior of magnetostrictive materials results from domain evolutions, often occurring at a microscopic scale. It is shown how to compute magnetization and magnetostriction curves by appraising the behavior of the underlying microstructures. The method hinges on an averaging device (Young measures), which allows one to pass from the microscopic to the macroscopic scale. The kinematical constraints on the accommodation of elastic effects are taken into account, and the role of material symmetry in the selection of energetically optimal microstructures is highlighted. Moreover, the effect of magnetoelastic coupling on the computation of magnetization curves is discussed.

I. INTRODUCTION

Specimens of magnetostrictive materials exhibit magnetic and elastic domains, which evolve under the action of applied magnetic fields and loads. Analyzing the mechanisms that govern these domain evolutions is a key step to understand the macroscopic response of magnetostrictive materials: The macroscopic deformations induced on these materials by applied magnetic fields result precisely from domain rearrangements, often occurring at a microscopic scale. In fact, the size of magnetic and elastic domains is typically rather small as compared to the size of the body in which they appear. As a consequence, domain patterns may result in complex geometries. Micromagnetics provides us with a rationale for the occurrence of fine domain patterns, based on energy minimization. Moreover, at least in principle, it could be used to predict the most energetically favored configurations under given applied fields and loads and, hence, for quantitative predictions of the macroscopic response of magnetostrictive materials. In practice, this program fails due to the complexity of the configurations to be computed.

In this article we report on recent progress in applying micromagnetics to predict virgin magnetization and magnetostriction curves. Our method, inspired by the work of James and Kinderlehrer,[1] is based on a simple idea: Only a few average properties of domain patterns are needed to compute magnetization and magnetostriction curves, and not all of the geometric details of domain patterns are needed to exactly quantify their energetics. We focus precisely on those features of domain patterns which are needed to select the energetically optimal ones, and to describe them in enough detail so that the macroscopic response can be characterized. Our analysis bears close similarities with those based on the classical article of Néel,[2] but there are also some significant differences. In particular, we do take into account the effect of magnetoelastic coupling on the prediction of magnetization curves.

II. MICROMAGNETICS

We adopt the large-body limit formulation of micromagnetics,[3] in which exchange energy is omitted. Following Clark,[4] we use the framework of linear elasticity, and we measure deformations through the linear strain $\mathbf{E}(x)=(\frac{1}{2})[\nabla\mathbf{u}(x)+\nabla^T\mathbf{u}(x)]$, where $\mathbf{u}(x)$ denotes the displacement of the point x of a body Ω. Moreover, we restrict our attention to an unloaded specimen (the case of applied surface tractions has been considered in Ref. 5). The state of Ω is described by a magnetization-deformation pair $(\mathbf{m},\mathbf{E})$, and we look for minimizers of the energy functional

$$G_{\mathbf{h}}(\mathbf{m},\mathbf{E})=\int_\Omega\{\varphi_{\mathrm{TOT}}[\mathbf{m}(x),\mathbf{E}(x)]-\mathbf{h}\cdot\mathbf{m}(x)\}dx + \frac{1}{2}\int_{\mathbb{R}^3}|\nabla u_{\mathbf{m}}(x)|^2\,dx. \tag{1}$$

Here $\mathbf{h}$ is a constant external magnetic field, while $-\nabla u_{\mathbf{m}}$ is the magnetic field generated by $\mathbf{m}$, defined as the solution of Maxwell equation $\mathrm{div}(-\nabla u_{\mathbf{m}}+\tilde{\mathbf{m}})=0$, where $\tilde{\mathbf{m}}$ is the extension of $\mathbf{m}$ to $\mathbb{R}^3$ which vanishes outside Ω. Moreover, we write

$$\varphi_{\mathrm{TOT}}(\mathbf{m},\mathbf{E})=\varphi(\mathbf{m})+\tfrac{1}{2}[\mathbf{E}-\mathbf{E}_0(\mathbf{m})]\cdot\mathbf{C}[\mathbf{E}-\mathbf{E}_0(\mathbf{m})], \tag{2}$$

where φ is the anisotropy energy density, $\mathbf{C}$ is the fourth-order tensor of elastic moduli, and $\mathbf{E}_0(\mathbf{m})$ is the stress-free strain corresponding to $\mathbf{m}$, i.e., the second-order tensor which, for given $\mathbf{m}$, is such that $\varphi_{\mathrm{TOT}}[\mathbf{m},\mathbf{E}_0(\mathbf{m})]\leq\varphi_{\mathrm{TOT}}(\mathbf{m},\mathbf{E})$ for every $\mathbf{E}$.

Crucial to our analysis are some properties of φ and $\mathbf{E}_0(\mathbf{m})$ dictated by material symmetry. Denoting by $\mathscr{P}$ the group of material symmetries of the material at hand, i.e., the set of orthogonal matrices $\mathbf{Q}$ such that $\varphi_{\mathrm{TOT}}(\mathbf{Qm},\mathbf{QEQ}^T)=\varphi_{\mathrm{TOT}}(\mathbf{m},\mathbf{E})$ for every $\mathbf{m}$ and $\mathbf{E}$, we have

$$\varphi(\mathbf{Qm})=\varphi(\mathbf{m}),\quad\text{and}\quad\mathbf{E}_0(\mathbf{Qm})=\mathbf{QE}_0(\mathbf{m})\mathbf{Q}^T,\quad\forall\mathbf{Q}\in\mathscr{P}. \tag{3}$$

We also remark that, in view of Eq. (2), $G_{\mathbf{h}}$ is the sum of a non-negative term (the energy due to magnetoelastic coupling), and of the energy

$$R_{\mathbf{h}}(\mathbf{m})=\int_\Omega\{\varphi[\mathbf{m}(x)]-\mathbf{h}\cdot\mathbf{m}(x)\}dx + \frac{1}{2}\int_{\mathbb{R}^3}|\nabla u_{\mathbf{m}}(x)|^2\,dx, \tag{4}$$

which would be associated with the magnetized body, were it to be considered rigid.

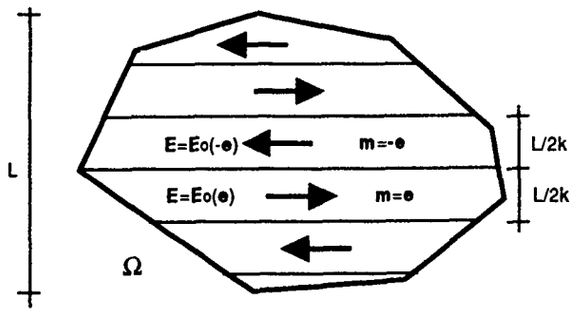

FIG. 1. The kth element of an energy-minimizing sequence for an unloaded specimen of uniaxial material under zero applied field.

III. MICROSTRUCTURES

The starting point of our analysis is the observation that the infimum of $G_{\mathbf{h}}$ may be unattainable in the space of admissible magnetization-deformation pairs. We illustrate this with an argument due to James and Kinderlehrer. We set $\mathbf{h}=0$, and we consider a uniaxial material with easy axis $\mathbf{e}$. Figure 1 shows the kth element of an energy minimizing sequence of magnetization-deformation pairs (note that the sequence is parametrized by the width of the layers, that the magnetization is always directed along the easy direction, and that the deformation is constant and it corresponds to a stress-free strain everywhere in Ω). By refining the width of the layers, we can drive the energy to its infimum I, which is $\varphi(\mathbf{e})$ times the volume of Ω. However, since there is no divergence-free magnetization field which takes only the values $\pm\mathbf{e}$, there is no configuration whose energy is exactly I. Thus, strictly speaking, the proposed minimization problem has no solution. In spite of this, the example gives a clear indication of how to proceed: a minimizer of G_0 should be described by the asymptotic behavior of an infinitely refining minimizing sequence, i.e., in a descriptive language, by a microstructure.

The notion of Young measure allows us to give a precise description of some of the asymptotic features of an infinitely refining sequence. Essentially, Young measures provide the precise mathematical description of the mixtures of magnetic phases introduced by Néel in Ref. 2. Indeed, the Young measure ν_x generated by a sequence of magnetizations $(\mathbf{m}_k)$, $k=1,2,...$, gives, at each point x of the body, the limiting distribution of the values of $\mathbf{m}_k$ in a vanishingly small neighborhood of x. For example, the Young measure generated by the sequence $(\mathbf{m}_k)$ of Fig. 1 is in fact independent of x and it can be written as

$$\nu=\tfrac{1}{2}\delta_{\mathbf{e}}+\tfrac{1}{2}\delta_{-\mathbf{e}}, \tag{5}$$

where $\delta_{\pm\mathbf{e}}$ is a Dirac mass centered at $\pm\mathbf{e}$. The physical meaning of Eq. (5) is the following: In the limit $k\to\infty$, $\mathbf{m}_k$ represents a microscopic arrangement of domains with the property that at every point of the body only domains with magnetization $\pm\mathbf{e}$ are present, and with equal volume fractions. The first moment of a Young measure generated by a sequence of magnetizations gives the average magnetization in a neighborhood of x, and its average over Ω gives the average magnetization of the whole specimen. For Eq. (5) we obtain zero, i.e., ν describes a demagnetized state. Similar arguments can be applied to sequences of deformations $\mathbf{E}_k$ and, in essence, our approach to the computation of magnetization and magnetostriction curves consists of a systematic application of the line of reasoning described above to cases in which an applied magnetic field is present. In particular, we note that if we are given a minimizing sequence $(\mathbf{m}_k,\mathbf{E}_k)$ of $G_{\mathbf{h}}$ for each value of the applied field $\mathbf{h}$, then the knowledge of the Young measures generated by the sequences $\mathbf{m}_k$ suffices to compute the corresponding magnetization curve.

Two remarks are in order. To clarify the physical meaning of infinitely refining sequences, we recall that the theory presented here is a limit theory for large specimens. Typically the ratio between the size of the domains and the size of the body in which they appear tends to zero as the latter increases. Since in the present theory this limiting process is represented on a reference body of fixed size, infinite refinement ensues. Our second remark concerns the problem of computing the energy of a microstructure. Put simply, the knowledge of the magnetic phases present in a microstructure, and of the corresponding volume fractions, does not provide enough information to compute its energy (in the example above, we carefully chose the orientation of the domain interfaces, and we also checked that no extra energy contributions arose from the magnetoelastic coupling). Thus, a model for magnetostrictive materials in which microstructures are described only through these quantities may lead to inaccurate predictions (see following section). It is indeed possible to characterize the energetics of microstructures without resolving them in their finest details. For this purpose, one needs not only Young measures, but also the H measures of Tartar.[6] The selection of optimal microstructures can thus be reduced to a minimization problem over Young measures and H measures. Here we follow the technically simpler alternative of computing minimizing sequences directly, and we use Young measures only to describe those of their features which are relevant for the computation of magnetization and magnetostriction curves. In this process, we do not neglect any energy contribution: In particular, we take into account both the magnetostatic and the magnetoelastic energy that may arise from jumps of the magnetization across adjacent domains.

IV. APPLICATIONS AND DISCUSSION

We illustrate our approach on a sample application. We consider a spherical specimen of uniaxial material, with anisotropy energy $\varphi(\mathbf{m})=\kappa[1-(\mathbf{m}\cdot\mathbf{e})^2]$ (we assume $|\mathbf{m}|=1$ and $\kappa>0$), under an applied field at 45° from the easy axis $\mathbf{e}$. We rely on the results of Ref. 3, where the corresponding minimization problem for $R_{\mathbf{h}}$ has been solved. The interesting regime is that of low field strengths, where minimizers of $R_{\mathbf{h}}$ are microstructures. Examples of the relevant minimizing sequences are shown in Fig. 2. They consists of layers, in each of which the magnetization takes one of two possible values (which depend on the applied field), say, $\mathbf{m}_1$ and $\mathbf{m}_2$. We obtain the minimizing sequences for $G_{\mathbf{h}}$ by setting every-

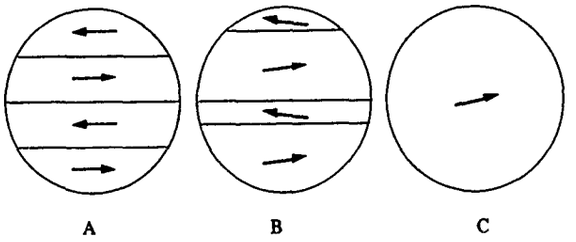

FIG. 2. Minimizing sequences for a spherical specimen of uniaxial materi with applied field at 45° from the (horizontal) easy axis. A,B,C correspond to increasing field strengths.

where in the specimen $\mathbf{E}(x)=\mathbf{E}_0[\mathbf{m}(x)]$. This leads to a discontinuous deformation field, which is, however, kinematically compatible if

$$\mathbf{E}_0(\mathbf{m}_1)-\mathbf{E}_0(\mathbf{m}_2)=\tfrac{1}{2}(\mathbf{a}\otimes\mathbf{e}_\perp+\mathbf{e}_\perp\otimes\mathbf{a}), \tag{6}$$

for some vector $\mathbf{a}$ (here $\mathbf{e}_\perp$ denotes the normal to the layer interfaces, while $\mathbf{a}\otimes\mathbf{b}$ denotes the matrix with components $a_i b_j$). This is indeed the case, and it is not hard to check. The "structural" reason behind this result is that $\mathbf{m}_2=\mathbf{R}\mathbf{m}_1$, where $\mathbf{R}$ is a 180° rotation about $\mathbf{e}_\perp$, and hence it is an element of $\mathscr{P}$. Thus, by Eq. (3), $\mathbf{E}_0(\mathbf{m}_2)=\mathbf{R}\mathbf{E}_0(\mathbf{m}_1)\mathbf{R}^T$.

We can conclude that, in the example considered, the minimizers of G_h correspond to stress-free states. Thus, if $(\mathbf{m},\mathbf{E})$ is a "minimizer" (possibly a microstructure) of G_h, then $\mathbf{m}$ is a "minimizer" of R_h (in fact, the unique minimizer of R_h, as shown in Ref. 3). These observations give rise to a strategy for computing magnetization and magnetostriction curves: The computation of the magnetization curve is reduced to the computation of the minimizers of R_h, and the magnetostriction curve is obtained by considering the stress-free strains associated with the minimizers of R_h. This is a standard procedure, and we have thus shown that, in the example considered, it is justified as an exact consequence of micromagnetics.

In spite of the fact that similar results can be proved for a surprisingly large class of materials,[7] the validity of the procedure outlined above is not universal. A simple example is that of iron, when an external field applied in the [111] direction. It is interesting to note that, close to saturation, the magnetization curve computed from the minimization of R_h differs substantially from the experimental measurements. In this regime the minimizers of R_h consist of mixtures of four magnetic "phases" which are not symmetry related, and whose associated stress-free strains cannot give rise to kinematically compatible deformations (a proof will appear in Ref. 7). We conjecture that, by taking into account the energy contribution due to the magnetoelastic coupling, a more realistic prediction of the magnetization curve can be obtained: Indeed, in order to compensate for the elastic energy stored in a stressed configuration, higher field strengths should be necessary to sustain a given average magnetization.

Magnetostriction of melt-spun Dy-Fe-B alloys

S. H. Lim, T. H. Noh, and I. K. Kang

The magnetostriction of melt-spun ribbons of $Dy_x(Fe_{1-y}B_y)_{1-x}$ ($x=0.2$, 0.25, 0.3; $0\leq y\leq 0.2$) alloys is systematically investigated as a function of the wheel speed during melt quenching. As the wheel speed increases from 10 to 50 m/s, the magnetic softness improves with the wheel speed rather continuously for the alloys with the Dy content $x=0.2$ and 0.25 but it exhibits a maximum at the wheel speed of 30 or 40 m/s for the alloys with the highest B content ($x=0.3$). The softness also improves with the B content for a fixed wheel speed. Homogeneous and ultrafine grain structure is observed for the first time even in the as-spun state when the ribbons of the alloy $Dy_{0.3}(Fe_{0.8}B_{0.2})_{0.7}$ are fabricated at the wheel speed of 30 m/s. The ribbon having the ultrafine grain structure exhibits good magnetic softness together with a high strain.

I. INTRODUCTION

Giant magnetostrictive rare-earth (R) -transition-metal (TM) -based alloys such as $TbFe_2$ were developed more than 2 decades ago.[1,2] The saturation magnetostriction λ_s, of $TbFe_2$ compound at room temperature is as large as 1753×10^{-6} (or 1753 ppm);[3] however, since the magnetocrystalline anisotropy of the alloys is also very large, a large magnetic field is usually required to obtain a large strain. In the practical point of view it is important to have a large magnetostriction at a low magnetic field. In an early effort in this direction, many workers attempted to reduce the magnetocrystalline anisotropy through alloy design, one notable example being the investigation of pseudobinary (R_1,R_2)-TM compounds. One main outcome from the investigation was the development of $Tb_{0.3}Dy_{0.7}Fe_2$ compound commercially known as Terfenol-D.[4]

Recently, attempts have been made to improve the softness of R-TM compounds by suitably controlling the microstructure of the compounds.[5–10] The main route to microstructural modification is rapid quenching from the melt. It has been reported by many workers that the grain refinement or amorphization by this method improves the softness of the alloys although, in some cases, this improvement has been done at the expense of reduced λ_s.[7,8] Very recently, R-TM alloys of thick-film type were also fabricated by sputtering and were reported to show good magnetic softness.[9,10] It is clear from these later studies that the softness of R-TM alloys is sensitively affected by the microstructure, although it is felt that not much systematic work has been done so far.

In order to see how the microstructure and hence the softness of R-TM alloys is affected by fabrication conditions, we systematically investigate the magnetostriction of melt-spun ribbons of R-Fe-B alloys. In the present work, the alloys selected were $Dy_x(Fe_{1-y}B_y)_{1-x}$ ($x=0.2$, 0.25, 0.3; $0\leq y\leq 0.2$). Similar work on Tb- and Sm-based alloys is in progress. The element B was added to the R-TM alloys, since it is known to affect the microstructure of as-spun ribbons.

II. EXPERIMENTAL DETAILS

The Dy-Fe-B alloys were arc melted in an Ar atmosphere. Subsequent melt spinning was carried out also in an Ar atmosphere. In the present experiments we fixed all the fabrication parameters except for the wheel speed which was varied over a wide range from 10 to 50 m/s. The melt temperature was maintained at just above the melting point of the respective alloys. The orifice diameter was about 0.5 mm and the chamber and ejecting Ar pressures were 2.1×10^{-2} and 1.85×10^{-1} MPa, respectively. The magnetostriction was measured by a three-terminal capacitance method at room temperature and at magnetic fields H up to 8 kOe. The microstructure was mainly examined by x-ray diffraction and, in some cases, by transmission electron microscopy (TEM).

III. RESULTS AND DISCUSSION

For the $Dy_{0.2}(Fe_{1-y}B_y)_{0.8}$ alloy system, it is observed from the results for λ vs H plots, not shown here due to space limitation, that λ increases very slowly with H at low fields, when ribbons of low-B alloys are fabricated at low wheel speeds (usually 30 m/s or less); however, the magnetic softness improves substantially with the increasing wheel speed and/or B content. These λ-H results are well explained by the x-ray-diffraction results. In low-B alloys, sharp diffraction peaks are seen at low wheel speeds indicating that crystalline phases with coarse grains exist, but, at high wheel speeds, the peaks are broadened indicative of the formation of finer grains. In high-B alloys, an amorphouslike broad pattern is observed even at low wheel speeds indicating that the glass-forming ability is increased by B addition. The value of λ in this alloy system is low, ranging from 30 to 60 ppm at 8 kOe. The crystalline phase is identified to be mainly Dy_6Fe_{23} compound with a small amount of $DyFe_3$.

For the alloy series $Dy_{0.25}(Fe_{1-y}B_y)_{0.75}$, the magnetic softness is observed to improve with the wheel speed, as is clearly demonstrated by the λ-H plots obtained at different wheel speeds for the $y=0.1$ alloy, as an example, shown in Fig. 1(a). The diffraction patterns for the same alloy are given in Fig. 1(b). Although the results are not shown here, the alloys with the other B content, except for the $y=0.2$ alloy, exhibit a similar λ-H behavior. This progressive improvement in the softness with the wheel speed is completely matched by the x-ray-diffraction patterns as shown in Fig. 1(b) from which it is observed that the peak intensity decreases and the peak width broadens continuously with the

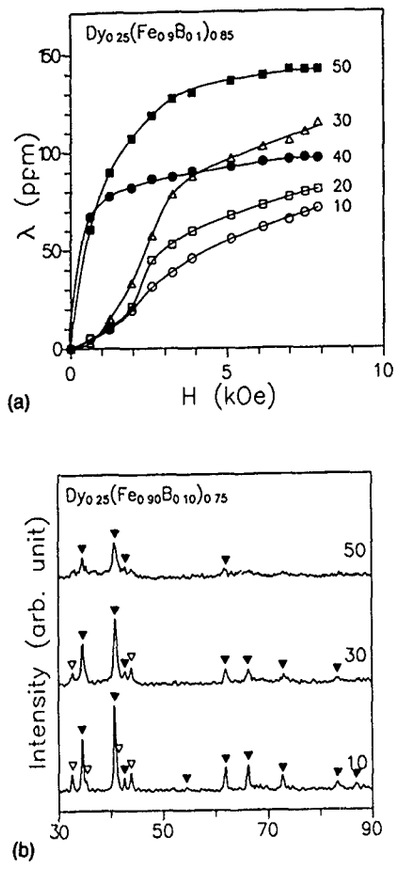

FIG. 1. (a) The λ-H plots for the alloy $Dy_{0.25}(Fe_{0.9}B_{0.1})_{0.75}$. (b) The x-ray-diffraction patterns for the same alloy as in (a). The $DyFe_2$ and $DyFe_3$ phases are indicated by the solid and open triangles, respectively. The numbers on the curves denote the wheel speed in m/s.

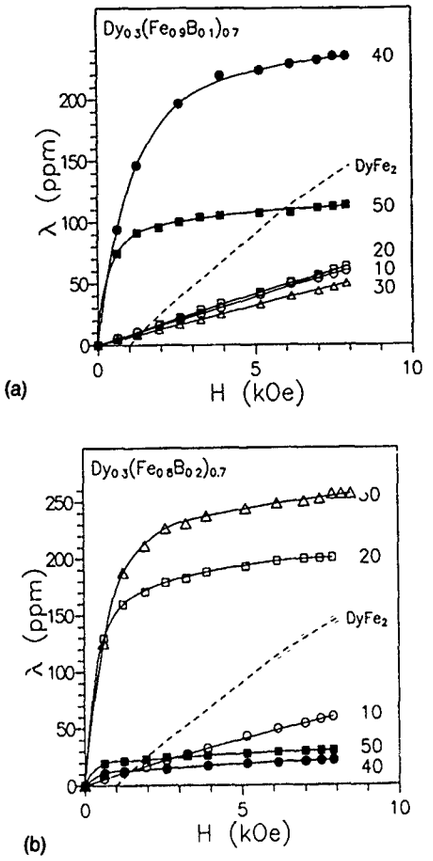

FIG. 2. The λ-H plots for the alloys (a) $Dy_{0.3}(Fe_{0.9}B_{0.1})_{0.7}$ and (b) $Dy_{0.3}(Fe_{0.8}B_{0.2})_{0.7}$. Also shown are the λ-H results for a bulk crystalline $DyFe_2$ for comparison (Ref. 3) (broken line). The numbers on the curves denote the wheel speed in m/s.

wheel speed. In the case of the $y=0.2$ alloy, the value of λ for the ribbons fabricated at the wheel speeds of 10 and 20 m/s is higher than that for the ribbons produced at the higher wheel speeds. The reason for this was originally thought to be due to the fact that, even at low wheel speed of 10 or 20 m/s, crystalline grains fine enough to result in good magnetic softness are formed at the large B content. The observed x-ray-diffraction patterns, however, do not seem to clearly support the assumption, since the peak intensity and the degree of line broadening do not vary greatly with the B content at the fixed wheel speed of 10 or 20 m/s. Further experiments are required to properly explain the high-λ values at the low wheel speeds in this high-B alloy.

The crystal structure of the $Dy_{0.25}(Fe_{1-y}B_y)_{0.75}$ series, which is determined by the x-ray-diffraction patterns, is observed to vary with the B content. Mostly the $DyFe_3$ phase exists in the B-free alloy and the $DyFe_2$ phase exists in the highest-B ($y=0.2$) alloy, and, in the alloys with the intermediate B content, the $DyFe_3$ and $DyFe_2$ phases coexist.

For the alloy system with the highest Dy content $Dy_{0.3}(Fe_{1-y}B_y)_{0.7}$, λ increases with the wheel speed, shows a maximum at the wheel speed of 40 m/s (30 m/s for the $y=0.2$ alloy), and then decreases with the further increase in the wheel speed. Some of the λ-H results are shown in Fig. 2(a) (for the alloy $y=0.1$) and Fig. 2(b) (for the alloy $y=0.2$). Although x-ray results are not shown here, the way in which the intensity and width of the x-ray peaks vary with the wheel speed is similar to that observed for the $Dy_{0.25}(Fe_{1-y}B_y)_{0.75}$ alloy system. The crystalline phase is determined to be mainly $DyFe_2$, a small amount of $DyFe_3$ being also observed for the alloys $y=0$ and 0.05. Also shown in Figs. 2(a) and 2(b) are the λ-H results for a bulk crystalline $DyFe_2$ for comparison.[3] No appreciable increase in λ of the bulk $DyFe_2$ is observed until $H=1$ kOe, after which λ increases with H almost linearly.

The decrease in λ at the high wheel speed of 40 or 50 m/s may be related to the presence of an amorphous phase. It is reported that the λ_s value of amorphous $DyFe_2$ is very low (38 ppm),[3] which is much lower than the value of 433 ppm at 25 kOe for the crystalline counterpart[3] as well as that of the present melt-spun ribbons fabricated at the optimum condition. It is therefore quite likely that λ decreases significantly by the formation of an amorphous phase. An amorphous phase can also be formed at the high wheel speed for the $Dy_{0.25}(Fe_{1-y}B_y)_{0.75}$ alloy system; however, since the main crystalline phase in $Dy_{0.25}(Fe_{1-y}B_y)_{0.75}$ is mainly $DyFe_3$ or a mixture of $DyFe_3$ and $DyFe_2$ (except for the high-B alloy where mainly $DyFe_2$ phase exists), as was already discussed, and the λ_s value of amorphous $DyFe_3$ is reported to be high (130 ppm),[5] which is similar to that for the ribbons fabricated

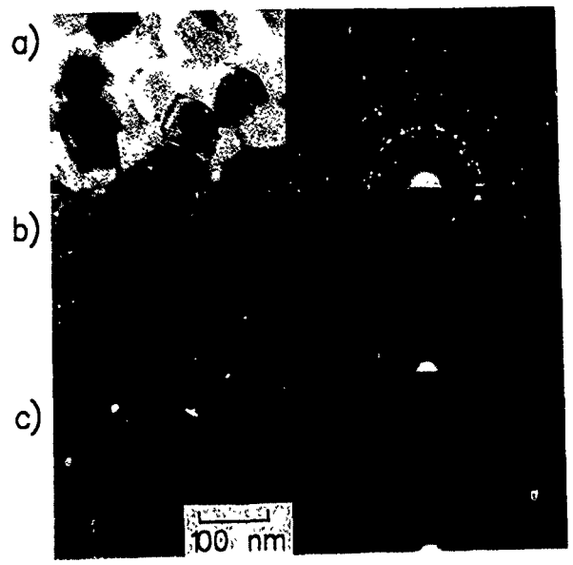

FIG. 3. Transmission electron micrographs (the bright-field images) and selected-area-diffraction patterns for the alloy $Dy_{0.3}(Fe_{0.8}B_{0.2})_{0.7}$ at the wheel speeds of (a) 10 m/s, (b) 30 m/s, and (c) 50 m/s.

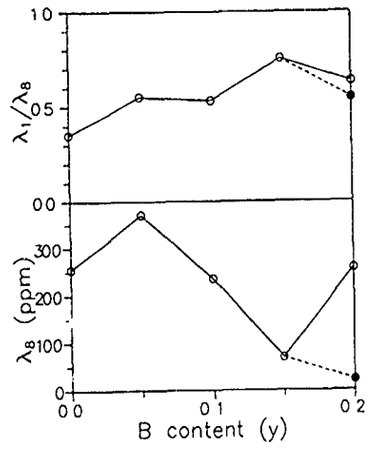

FIG. 4. The values of λ_1/λ_8 and λ_8 (where λ_1 and λ_8 are the values of λ at 1 and 8 kOe, respectively) as a function of the B content y in the alloy system $Dy_{0.3}(Fe_{1-y}B_y)_{0.7}$. The data with the open circles are for the wheel speeds which yielded the largest λ_1 (40 m/s for the alloys $y \leq 0.15$ and 30 m/s for the alloy $y=0.2$). In the $y=0.2$ alloy, the results at the wheel speed of 40 m/s are also shown and are indicated by the solid circles.

at the optimum wheel speed, the presence of an amorphous phase will not greatly affect the λ value. The assumption that the decrease in λ at the high wheel speed is related to the amorphous phase is supported by the present x-ray results, since amorphouslike patterns appear to be seen together with crystalline peaks at the high wheel speed. Amorphouslike patterns become clearer as the B content increases.

In order to examine the microstructure further, TEM experiments were conducted and some of the results are shown in Fig. 3 for the $Dy_{0.3}(Fe_{0.8}B_{0.2})_{0.7}$ alloy. From the TEM results, two important points can be noted: First, an amorphous phase is observed by TEM, as is evidenced by the halo pattern at the wheel speed of 50 m/s; second, the more important point is that, at the wheel speed of 30 m/s, homogeneous and ultrafine crystalline grains are formed. The grain size is estimated to be 10–20 nm. This is the first observation of homogeneous and ultrafine grains, to our knowledge, in the as-spun state, although similar ultrafine grains were previously observed for the Tb-Fe-B alloy system by annealing precursor amorphous alloy ribbons.[8]

In order to see how the magnetic softness and the value of λ vary with the B content, the results for λ_1/λ_8 (where λ_1 and λ_8 are the values of λ at 1 and 8 kOe, respectively) and λ_8 as a function of the B content are shown in Fig. 4 for the $Dy_{0.3}(Fe_{1-y}B_y)_{0.7}$ alloy system. The ratio λ_1/λ_8 is used to measure the degree of magnetic softness. For each B content, we plot data for that wheel speed which yielded the highest strain at 1 kOe (largest λ_1), which was obtained at the wheel speed of 40 m/s for the alloys with the composition $y \leq 0.15$ and the wheel speed of 30 m/s for the $y=0.2$ alloy. In the $y=0.2$ alloy, the results at the wheel speed of 40 m/s are also shown in the figure in order to compare the results for the ribbons fabricated at the same wheel speed. The reason for the highest λ_1/λ_8 ratio at $y=0.15$ is related to the presence of a magnetically soft amorphous phase. The high ratio, however, is achieved at the cost of very low λ_8 value. With the same reasoning, the λ_1/λ_8 ratio of the $y=0.2$ alloy at the wheel speed of 40 m/s is expected to be large but it is observed to be small. This is because the value of λ itself is so low that the contribution from the volume magnetostriction after saturation becomes appreciable, even though the value of volume magnetostriction (which is usually indicated by the slope $d\lambda/dH$ after the saturation) is similar to each other. The ribbon having the ultrafine grain structure ($y=0.2$) exhibits good magnetostrictive properties; good magnetic softness ($\lambda_1/\lambda_8=0.66$) and a high strain ($\lambda_8=260$ ppm).

IV. CONCLUSION

In conclusion, λ-H behavior of the melt-spun ribbons of Dy-Fe-B alloys is investigated as a function of the wheel speed and alloy composition. The homogeneous and ultrafine grain structure is observed for the first time even in the as-spun state when the ribbons of the alloy $Dy_{0.3}(Fe_{0.8}B_{0.2})_{0.7}$ are fabricated at the wheel speed of 30 m/s. The ribbons having the ultrafine grain structure are observed to exhibit good magnetostrictive properties.

Magnetic properties and magnetostriction in grain-oriented $(Tb_xDy_{1-x})(Fe_{1-y}Mn_y)_{1.95}$ compounds

T. Kobayashi, I. Sasaki, T. Funayama, and M. Sahashi
R&D Center, Toshiba Corporation, 1 Komukai, Toshiba-cho, Saiwai-ku, Kawasaki-210, Japan

The magnetic properties and magnetostriction in grain-oriented $(Tb_xDy_{1-x})(Fe_{1-y}Mn_y)_{1.95}$ compounds with $0.3 \leq x \leq 0.5$, $0 \leq y \leq 0.2$ prepared by the Bridgman method have been investigated. It is confirmed that the Mn substitution not only lowers the spin reorientation temperature but also enhances $\lambda\langle 100\rangle$. This large $\lambda\langle 100\rangle$ is contradictory to the single-ion model. For $Tb_{0.5}Dy_{0.5}(Fe_{0.9}Mn_{0.1})_{1.95}$ compound, no spin reorientation, which induces the sharp drop in the magnetostriction is seen in the temperature range from 77 to 400 K. In addition, by choosing the appropriate compressive stress, the quite excellent thermal stability and the large magnetostriction of 2000 ppm in the low applied field can be realized in the $Tb_{0.5}Dy_{0.5}(Fe_{0.9}Mn_{0.1})_{1.95}$ compound. These features make $Tb_{0.5}Dy_{0.5}(Fe_{0.9}Mn_{0.1})_{1.95}$ a promising material applicable to the various giant magnetostrictive actuators.

I. INTRODUCTION

The Laves phase compounds, rare earth with iron (RFe_2), are well known for their giant magnetostriction. In the pseudobinary compounds, $Tb_xDy_{1-x}Fe_2$, the spin reorientation takes place at a specific temperature. For $Tb_{0.27}Dy_{0.73}Fe_2$, the spin reorientation takes place near room temperature. In the compounds with cubic symmetry, the easy magnetization direction lies along the crystallographic axis $\langle 111\rangle$ at higher temperature, while $\langle 100\rangle$ is the easy magnetization direction at lower temperature.[1,2] Because the magnetostriction constant along $\langle 111\rangle$, $\lambda\langle 111\rangle$, is much larger than that along $\langle 100\rangle$, $\lambda\langle 100\rangle$, a large change in magnetostriction occurs around the spin-reorientation temperature.

On the other hand, the Mn substitution for Fe in $(TbDy)Fe_2$ enhances its magnetostriction at room temperature and also lowers its spin-reorientation temperature by changing the magnetocrystalline anisotropy.[3] Furthermore, the Mn-containing compound has the larger magnetostriction constant $\lambda\langle 100\rangle$ than the Mn free compounds;[4] however, the detailed behavior of the magnetostriction and the related phenomena is still ambiguous due to the lack of data obtained from the single crystals. The purpose of this article is to investigate the magnetocrystalline anisotropy and magnetostriction based on the data obtained from the $(TbDy)(FeMn)_2$ single-crystal samples and to discuss the spin-reorientation phenomena and the related magnetostriction behaviors.

II. EXPERIMENT

$Tb_xDy_{1-x}(Fe_{1-y}Mn_y)_{1.95}$ samples with $0.3 \leq x \leq 0.5$, $0 \leq y \leq 0.2$ were prepared by the Bridgman method. In preparing samples, a h-BN crucible was used. The solidification rate was 29 mm/h. The samples were heat treated in vacuum at 950 °C for 5 h. The crystallographical direction of the samples was determined by the Laue method. The metallographic observation were carried out by the scanning electron microscope (SEM).

The torque measurements were carried out in the temperature range from 77 to 400 K, using a torque magnetometer. The magnetic field was applied up to 1.7 T. The (110) plane, which contains all of the principal crystallographic axis, was chosen for the torque measurements. The magnetostriction along the $\langle 111\rangle$ and $\langle 100\rangle$ crystallographic direction was measured by a standard strain gauge technique, using $\phi 3 \times 0.5$ mm (disk) and $\phi 6 \times 10$ mm (cylindrical rod). The cylindrical samples were provided for the magnetostriction measurements under static compressive stress from 0.8 to 20.2 MPa with the applied field up to 0.4 T. Magnetostriction along the $\langle 111\rangle$ and $\langle 100\rangle$ without the compressive stress were measured with the applied field up to 1.7 T, using the disk samples.

III. RESULTS AND DISCUSSIONS

The metallographic observation by SEM shows that the samples prepared by the Bridgman method have regular platelet microstructures. Their crystallographic $\langle 111\rangle$ axis tilt about 10°–20° from their rod axis. The prepared samples have enough qualities for the torque measurements with one exception. In the Mn-free and high-Tb-content case of $Tb_{0.5}Dy_{0.5}Fe_2$, a planar dendrite microstructure is partially observed and the crystallographic direction deviates part by part in the prepared sample, while $Tb_{0.5}Dy_{0.5}(Fe_{0.9}Mn_{0.1})_{1.95}$ dose not show such a disorder. This suggests that the Mn substitution modifies the phase diagram and leads to the change in the solidification process and the microstructure of the sample, particularly in the high-Tb-content region. Figure 1 shows the temperature dependencies of the magnetostrictions at 0.1 T for the Mn-containing and Mn-free polycrystal materials.[5] In the figure the magnetostrictions are normalized by their room-temperature values. For $Tb_{0.3}Dy_{0.7}Fe_{1.93}$ and $Tb_{0.3}Dy_{0.7}(Fe_{0.8}Mn_{0.2})_{1.93}$, sharp magnetostriction drops can be seen around the spin-reorientation temperature, where the easy magnetization direction changes from $\langle 111\rangle$ to $\langle 100\rangle$; but, it starts at 300 K for $Tb_{0.3}Dy_{0.7}Fe_{1.93}$ while it starts at 220 K for $Tb_{0.3}Dy_{0.7}(Fe_{0.8}Mn_{0.2})_{1.93}$. So, the Mn substitution for Fe lowers the spin-reorientation temperature. It is also noted that the magnetostriction of $Tb_{0.3}Dy_{0.7}(Fe_{0.8}Mn_{0.2})_{1.93}$ in the lower-temperature region is larger than that of $Tb_{0.3}Dy_{0.7}Fe_{1.93}$. For the high-Tb-content $Tb_{0.5}Dy_{0.5}(Fe_{0.9}Mn_{0.1})_{1.93}$, such a magnetostriction drop is never seen in the temperature range from 77 to 400 K.

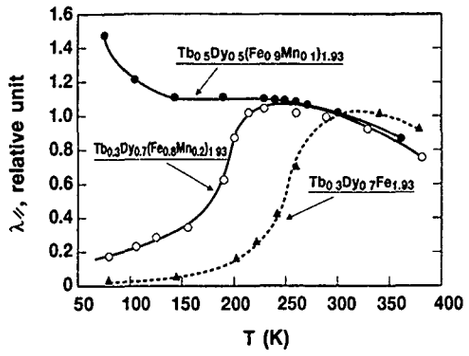

FIG. 1. Temperature dependences of the magnetostriction at 0.1 T for the Mn-containing and Mn-free polycrystal materials.

Figure 2 shows the temperature dependence of the free-energy difference between the magnetization along the ⟨111⟩ axis and that along ⟨100⟩ axis for $Tb_xDy_{1-x}(Fe_{0.9}Mn_{0.1})_{1.95}$ with $x=0.3$, 0.4 and 0.5. With decreasing temperature the energy difference increases at first and then it decreases. Its minimum corresponds to the spin-reorientation temperature. From this result we can confirm that the increase of the Tb content decreases the spin-reorientation temperature and that the spin reorientation does not take place in the temperature range from 77 to 400 K for $Tb_{0.5}Dy_{0.5}(Fe_{0.9}Mn_{0.1})_{1.95}$. Figure 3 shows the temperature dependence of the magnetostriction λ⟨111⟩ and λ⟨100⟩ for $Tb_{0.4}Dy_{0.6}Fe_{1.95}$ and $Tb_{0.4}Dy_{0.6}(Fe_{0.8}Mn_{0.2})_{1.95}$. The temperature is normalized by the Curie temperature T_c. In Fig. 3(a) the magnetostriction λ⟨111⟩ of both $Tb_{0.4}Dy_{0.6}Fe_{1.95}$ and $Tb_{0.4}Dy_{0.6}(Fe_{0.8}Mn_{0.2})_{1.95}$ behaves in almost the same manner. The drop of magnetostriction of both samples takes place around $T/T_c=0.2$ under the applied magnetic field of 0.2 T; however, the behavior of the λ⟨100⟩ is quite different. As can be seen in Fig. 3(b), λ⟨100⟩ of $Tb_{0.4}Dy_{0.6}Fe_{1.95}$ shows little temperature dependence although a little jump of the λ⟨100⟩ is seen around $T/T_c=0.2$ due to the change in the easy magnetization direction from ⟨111⟩ to ⟨100⟩. This indicates that the intrinsic magnetostriction along ⟨100⟩ axis is small for $Tb_{0.4}Dy_{0.6}Fe_{1.95}$. To the contrary the jump of the λ⟨100⟩ is

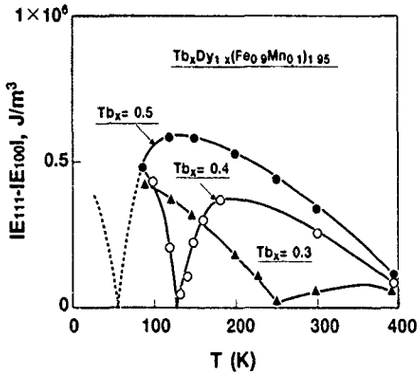

FIG. 2. Temperature dependence of the free-energy difference between the magnetization along ⟨111⟩ axis and that along ⟨100⟩ axis for $Tb_xDy_{1-x}(Fe_{0.9}Mn_{0.1})_{1.95}$ with $x=0.3$, 0.4 and 0.5.

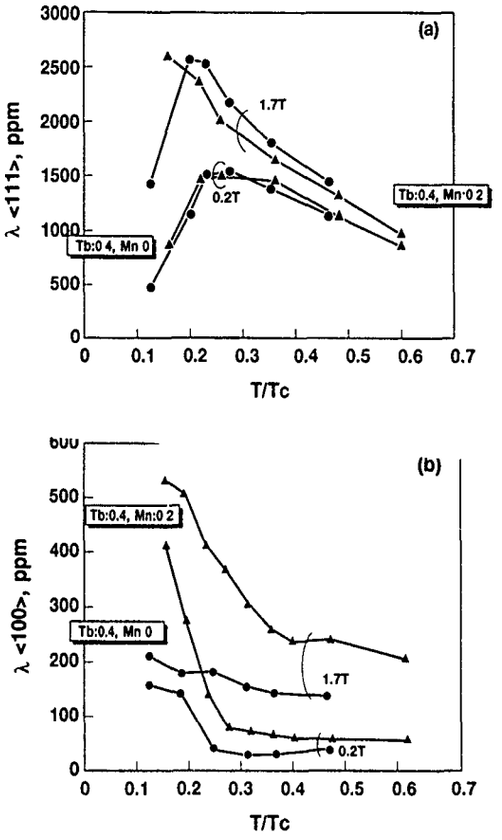

FIG 3. Temperature dependence of the magnetostriction λ⟨111⟩ and λ⟨100⟩ for $Tb_{0.4}Dy_{0.6}Fe_{1.95}$ and $Tb_{0.4}Dy_{0.6}(Fe_{0.8}Mn_{0.2})_{1.95}$: (a) λ⟨111⟩ and (b) λ⟨100⟩.

very large for $Tb_{0.4}Dy_{0.6}(Fe_{0.8}Mn_{0.2})_{1.95}$. Its λ⟨100⟩ reaches 500 or 600 ppm in the low-temperature region. This result suggests that the intrinsic magnetostriction along ⟨100⟩ axis is very large for $Tb_{0.4}Dy_{0.6}(Fe_{0.8}Mn_{0.2})_{1.95}$ and that the enhancement of λ⟨100⟩ results from the Mn substitution. The single-ion model proposed by Cullen and Clark[6] predicts the small λ⟨100⟩ by neglecting the transition-metal contributions. This is confirmed to be true for the Mn-free samples in our experiments, but the Mn-containing case is contradictory. This result suggests the importance of constructing a model to include the transition-metal contributions for explaining the behavior of the giant magnetostrictive materials properly.

Figure 4 shows the temperature dependence of λ⟨111⟩ at 1360 kA/m (17 kO) for $Tb_{0.3}Dy_{0.7}Fe_{1.95}$ and $Tb_{0.5}Dy_{0.5}(Fe_{0.9}Mn_{0.1})_{1.95}$. As the easy magnetization direction changes from ⟨111⟩ to ⟨100⟩, λ⟨111⟩ of $Tb_{0.3}Dy_{0.7}Fe_{1.95}$ decreases with decreasing temperature. On the other hand, λ⟨111⟩ of $Tb_{0.5}Dy_{0.5}(Fe_{0.9}Mn_{0.1})_{1.95}$ monotonically increases with decreasing temperature owing to the spin-reorientation-free characteristics. Its λ⟨111⟩ is 1500 ppm at the room temperature and reaches as high as 3250 ppm at 77 K. The high λ⟨111⟩ value and the spin-reorientation-free characteristics leading to the high thermal stability are very desirable for the applications of this giant magnetostrictive material.

Figure 5 shows the magnetostriction under the compressive stress of 0.8, 8.3, and 20.2 MPa as a function of the applied field for $Tb_{0.5}Dy_{0.5}(Fe_{0.9}Mn_{0.1})_{1.95}$. Under the compressive stress of 0.8 MPa, $\Delta l/l\langle 111\rangle$ is 1200 ppm at the

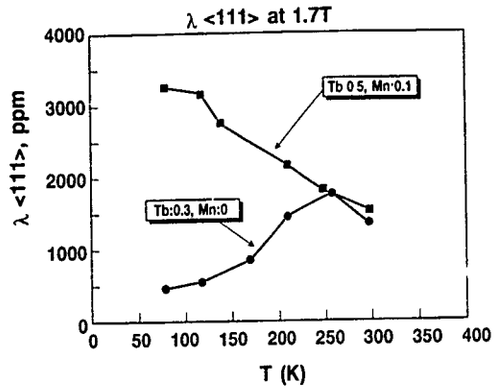

FIG. 4 Temperature dependence of λ⟨111⟩ at 1.7 T for $Tb_{0\,3}Dy_{0\,7}Fe_{1\,95}$ and $Tb_{0\,5}Dy_{0\,5}(Fe_{0\,9}Mn_{0\,1})_{1\,95}$.

room temperature [Fig. 5(a)]. When the compressive stress is increased to 8.3 MPa, $\Delta l/l\langle 111\rangle$ reaches to 2000 ppm even in the low-magnetic-field region. At 77 K [Fig. 5(b)], λ⟨111⟩ becomes as large as 1700 ppm under the compressive stress of 0.8 MPa; however, the $\Delta l/l\langle 111\rangle$ versus the applied field curve changes little under the compressive stress of 8.3 MPa compared to that at the room temperature. Therefore, by choosing the appropriate compressive stress the very good thermal stability of the magnetostriction can be obtained in $Tb_{0\,5}Dy_{0.5}(Fe_{0.9}Mn_{0.1})_{1\,95}$. The thermal stability as well as the large magnetostriction in the low applied field region makes $Tb_{0.5}Dy_{0\,5}(Fe_{0\,9}Mn_{0\,1})_{1.95}$ a promising candidate applicable to the various giant magnetostrictive actuators.

In this connection, the hysteresis in the magnetostriction curve of $Tb_{0\,5}Dy_{0.5}(Fe_{0\,9}Mn_{0.1})_{1.95}$ is a little larger than that of $Tb_{0.3}Dy_{0.7}Fe_2$.[7] This is probably due to its higher Tb content which increases the magnetocrystalline anisotropy. So, this feature should be taken into consideration when designing the actuators.

IV. CONCLUSION

Based on the data obtained from the single-crystal measurements, it is confirmed that the Mn substitution does not only lowers the spin-reorientation temperature but also enhances λ⟨100⟩. This large λ⟨100⟩ is contradictory to the single-ion model.

$Tb_{0\,5}Dy_{0\,5}(Fe_{0\,9}Mn_{0\,1})_{1\,95}$ compound has no spin-reorientation temperature in the temperature range from 77 to 400 K. In addition, by choosing the appropriate compressive stress, the quite excellent thermal stability and the large

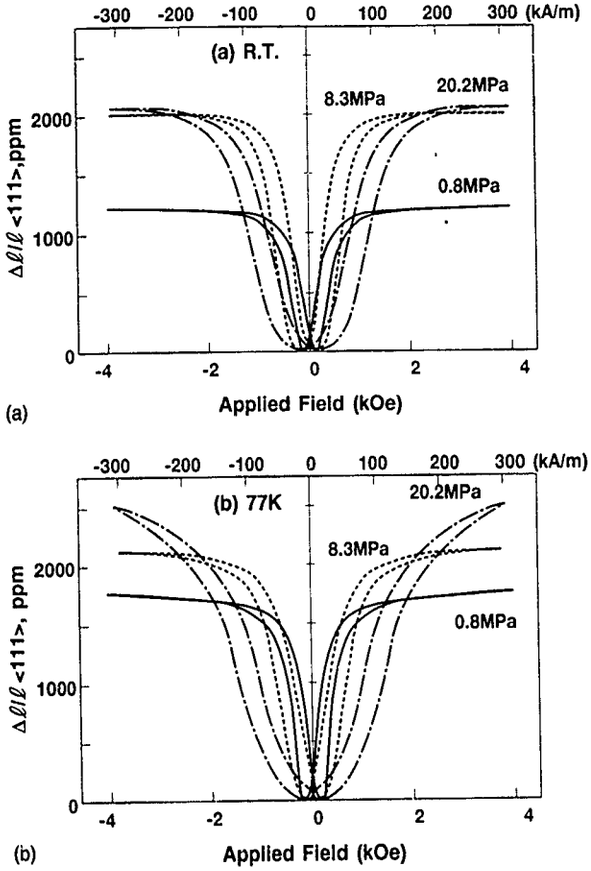

FIG. 5. Magnetostriction under the compressive stress of 0.8, 8.3, and 20.2 MPa as a function of the applied field for $Tb_{0\,5}Dy_{0\,5}(Fe_{0\,9}Mn_{0\,1})_{1\,95}$ at (a) room temperature and (b) at 77 K.

magnetostriction of 2000 ppm in the low applied field can be realized in the $Tb_{0\,5}Dy_{0.5}(Fe_{0\,9}Mn_{0.1})_{1.95}$ compound. These features make $Tb_{0\,5}Dy_{0\,5}(Fe_{0\,9}Mn_{0.1})_{1\,95}$ a promising material applicable to the various giant magnetostrictive actuators.

Stress effect on the magnetization of Dy in the $Dy/DyFe_2$ eutectic

J. P. Teter, S. F. Cheng, and J. R. Cullen
NSWC-White Oak, Silver Sring, Maryland 20903-5640

The magnetization of the alloy $DyFe_{1.5}$ was studied as a function of temperature from 50 to 300 K in a range of magnetic field up to 10 kOe. Metallographic studies showed the existence of a eutectic phase containing both $DyFe_2$ and elemental Dy embedded in the $DyFe_2$ matrix. The presence of elemental Dy was observed in the magnetization data through a cusp in the temperature dependence of the magnetization at 178 K and an increase of the magnetization starting at 130 K and continuing to 80 K. While the first feature occurs at precisely the Néel temperature of bulk Dy, the second contrasts with the jump at the Curie temperature of 89 K observed in low fields in bulk single-crystal Dy. The more gradual increase in magnetization observed in the $DyFe_{1.5}$ alloy is attributed to variations in stress to which the Dy is subjected. The temperature dependence of the magnetic moment from 80 to 130 K is modeled as arising from a collection of Dy particles of varying Curie temperatures. This variation is in turn caused by the stress distribution. Curie temperature distributions are found for a range of magnetic fields and then are extrapolated to zero field in order to eliminate the effect of field. The calculations indicate that a significant amount of the Dy remains in the helimagnetic phase down to zero temperature.

I. BACKGROUND

Dy metal, which forms in the hexagonal close-packed structure, undergoes a transition from a paramagnetic to a helical phase at a temperature T_N=179 K. Below T_N, the magnetic moment spirals in the basal plane, with the propagation vector parallel to the c axis. The pitch angle of the spiral varies from 43.2° just below T_N to 26.5° at the transition temperature to ferromagnetism T_C. T_C is magnetic-field (H) dependent; it is equal to 89 K in zero field and rises to T_N at 10 kOe, completely erasing the helical phase at that field. At T_C, the magnetic moment is observed to abruptly increase. The jump in moment depends on the value of T_C; it decreases from a maximum of 300 emu/g at 89 K to zero at T_N.[1] T_C has also been observed to be stress dependent. Compressive stress applied in the basal plane of a single crystal of Dy increased T_C at a rate of 10 K/kbar.[2] In recent experiments on epitaxially grown Dy,[3] T_C increased with basal-plane compression at the same rate as was observed in the earlier stress measurements. On the other hand, T_C decreased more rapidly for Dy grown on increasingly expanded substrates,[4] so that the ferromagnetic state disappeared completely when the lattice-mismatch strain exceeded 10^{-3}, equivalent to a tensile stress of the order of 0.1 kbar.[4] This sensitivity to stress should manifest itself in materials in which elemental Dy is present in a disordered manner such as polycrystalline samples or as part of a multiphase material. Here we report our results of magnetic studies of $DyFe_{1.5}$, an alloy consisting of Laves-phase $DyFe_2$ and a eutectic phase containing both $DyFe_2$ and elemental Dy. An optical picture of the grain-boundary area of a polished sample is shown in Fig. 1. The central region shows the admixture of Dy and $DyFe_2$ surrounded by large crystals of primary $DyFe_2$ with random orientations. We interpret the temperature dependence of our magnetic moment measurements in terms of a model in which the Dy is assumed to exist in the eutectic as a randomly oriented set of particles of varying shapes, thereby subjected to stress of random strength, orientation, and sign. Guided by the results of Ref. 2–4, we expect that those particles which find themselves under a net basal-plane compression (or a c-axis tension) will display an enhanced T_C, and visa versa; however, other types of stresses are present in $DyFe_{1.5}$ and some of those will also change T_C. The magnetic moment data of themselves are not capable of distinguishing between the stress components; we extract only a probability per unit temperature that a particle will undergo a transition from the helimagnetic to the ferromagnetic phase at a given temperature. In the following, we briefly describe the experimental details. We then discuss the model and apply it to determine the probability distributions at zero field. In order to accomplish this, we extrapolate the distributions obtained at fields of 3, 2, 1, and 0.5 kOe to zero field.

II. MAGNETIZATION MEASUREMENTS

The magnetic moment of several disk-shaped samples with 0.5 cm diameter and 0.03 cm thickness cut from a rod

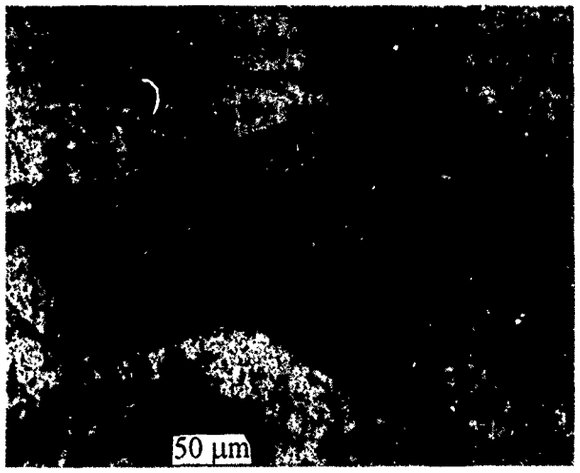

FIG 1. Optical photograph of $DyFe_{1.5}$. Surface was polished to $\frac{1}{4}$ μm The dark central region consists of elemental Dy intermixed with lighter colored $DyFe_2$ crystals. The outer region consists of the primary $DyFe_2$ phase with random crystallographic orientations.

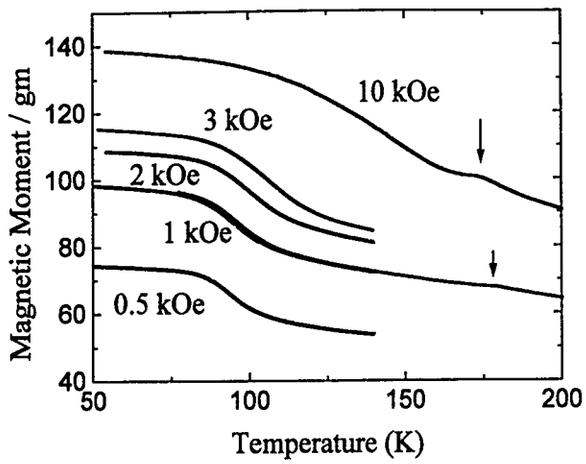

FIG. 2. Magnetic moment per gram of $DyFe_{1.5}$ vs temperature from 50 to 140 K or to 200 K. Each curve was taken at a constant applied magnetic field in the plane of the sample. Magnetic-field strengths were 10, 3, 2, 1, and 0.5 kOe (top to bottom). The arrows mark the onset of the helimagnetic phase at 10 and 1 kOe. The 1 kOe helimagnetic transition is at 178.5(±1) K.

of $DyFe_{1.5}$ was determined as a function of temperature T. The measurements were made as the samples were heated from 50 to 300 K. The moment was also measured as the temperature was held fixed at 50, 77, 256, and 300 K and H was swept between ±10 kOe. All measurements were made with the field in the plane of the disk. Plots of magnetic moment per gram versus T for $H=0.5$, 1, 2, 3, and 10 kOe are shown in Fig. 2. The onset of the Dy helimagnetic phase at $T=T_N$ is evident in all the data sets collected; shown are the 1 and 10 kOe plots in which it appears as a cusp at 178 K for $H=1$ kOe, the Néel temperature of bulk Dy. We interpret the rise in moment at lower T, progressively sharper as H decreases, as the onset of ferromagnetic order in Dy in the eutectic. The decrease in moment at 0.5 kOe results from the increase in the anisotropy of $DyFe_2$, which prevents its moment from saturating at low fields. We have observed an orientation dependence of the magnetization of our samples with respect to the direction of H, indicating the presence of texture. The maximum difference in moment is roughly 10% of the average moment. We therefore regard this as a small deviation from isotropy, and neglect texture in what follows.

III. DISCUSSION

Taking the $DyFe_{1.5}$ alloy as composed of elemental Dy and $DyFe_2$, we estimate that the Dy phase comprises 16.5% of the sample weight. The $T=0$ K saturation moment, using 350 and 140 emu/g as the moment, respectively, of Dy and $DyFe_2$,[5] is calculated to be 175 emu/g. To determine the theoretical remanent moment, we have assumed that the Dy moments all lie in the basal plane, while those of $DyFe_2$ all lie in ⟨100⟩ directions at remanence (see Table I). The value is then estimated to be 142.6 emu/g in comparison to 145 emu/g experimentally determined by extrapolating the 10 kOe curve of Fig. 2 to 0 K. The close agreement between these two values makes plausible the model of magnetically independent randomly oriented particles or crystallites of Dy

TABLE I. Remanent moments of polycrystals as a fraction of saturation moment.

Easy axis	Remanence	Crystal structure
[100][a]	0.831	cubic
[111]	0.866	cubic
$a(b)$	0.750	hexagonal
c	0.500	hexagonal
(a,b) plane[a]	0.785	hexagonal

[a]The cases assumed for calculating the remanent moments.

and $DyFe_2$. We now attempt to understand the temperature dependence of the moment for temperatures below the Néel point as follows. The random orientation and position of the Dy crystals in the eutectic places them under a distribution of stress which raises T_C for some, while reducing that of others. The probability that a given crystallite will undergo a spiral to ferromagnetic transition can be simply related to the temperature derivative of the moment. To do this, we imagine that, at a certain T and H a crystallite whose T_C is greater than T will have achieved the bulk moment consistent with that T and H. Thus, the moment per gram is

$$\sigma(T)\cong\Delta\sigma\int_0^{T_N} dT_C S(T-T_C)f(T_C)+\sigma_b, \tag{1}$$

where $S(T-T_C)=1$, $T-T_C\leq 0$; $S(T-T_C)=0$, $T-T_C>0$; and $f(T_C)dT_C$ is the probability of finding a Dy particle with that T_C in the range dT_C. $\Delta\sigma$ is the jump in the single-crystal moment. Then,

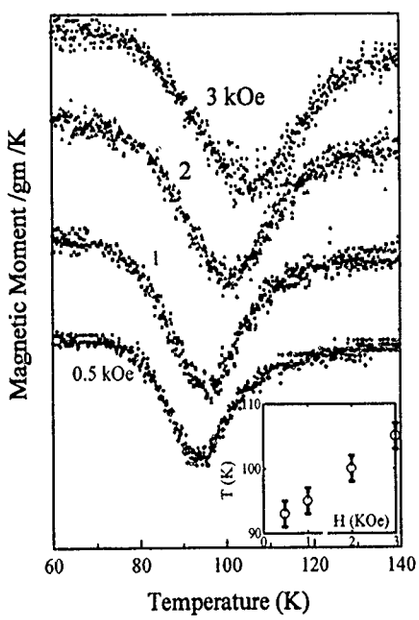

FIG. 3. Composite graph of the temperature derivative of the magnetic moment per gram of $DyFe_{1.5}$ at applied magnetic fields of 3, 2, 1, and 0.5 kOe (top to bottom). The vertical scale is shifted for each set of data. The 0.5 kOe curve was integrated from $T=0$ to $T=125$ K. The zero-derivative line in this case lies above the curve at low T, but decreases with increasing T, meeting the data at $T=125$ K. Each curve starts at near zero slope and minimizes at −0.7 magnetic moment/g/K. The inset is a plot of the estimated temperature minimum for each case, vs applied field.

$$\frac{d\sigma}{dT} = -\Delta\sigma f(T), \tag{2}$$

where we drop possible contributions to the derivative from the temperature dependence of $\Delta\sigma$ or σ_b, the background moment, the latter coming mainly from that of $DyFe_2$.

Plots of $d\sigma/dT$ taken from the moment measured on the disk at $H=0.5$, 1, 2, and 3 kOe are shown in Fig. 3. According to Eq. (2), they are proportional to $f(T)$, at the stated H. Ideally, to uncover the effects of stress alone on the Dy particles we need to eliminate the field effect entirely, and have $d\sigma/dT$ at $H=0$. Since the shapes of the curves in Fig. 3 do not change once H is <1 kOe, we take the 0.5 kOe curve as representative, except for an overall downward shift of 2 K, of $f(T)$. Using the single-crystal value of $\Delta\sigma$ times the weight percent of Dy in $DyFe_{1.5}$ (47.1 emu/g), and integrating the 0.5 kOe curve of Fig. 3 from 80 to 125 K, we obtain 0.25 as the probability of finding a particle with its T_C in that range of T. Since it is unlikely to find particles with higher T_C (T_C=130 K would require a compressive stress of 4 kbar) we conclude that 75% of the Dy particles have $T_C<80$ K. An estimate of the area under the same curve from 0 to 80 K gives another 25% of the particles in this range of T. Thus the remaining 50% of the Dy particles are in the helimagnetic phase, at all $T<T_N$.

IV. SUMMARY

We have discussed the temperature dependence of the magnetic moment of $DyFe_{1.5}$ below the Néel point as mainly due to a collection of Dy particles in the eutectic subjected to stresses which vary from particle to particle. The effect of the distribution of the stress is to spread the ferro- to helimagnetic transition over a range of temperatures. Our analysis of the data in terms of the model described above leads us to conclude that a significant number of the particles remain helimagnetic down to zero temperature. This accords with the result of measurements on epitaxial Dy, that basal-plane extensions of the order of 10^{-3} are sufficient to suppress the ferromagnetic phase. Such strains translate into stresses of 0.1 kbar, which are likely to be present in the $DyFe_{1.5}$ eutectic.

Direct measurements of magnetostrictive process in amorphous wires using a scanning tunneling microscope (abstract)

J. L. Costa, J. Nogués, and K. V. Rao
Department of Condensed Matter Physics, The Royal Institute of Technology, S-100 44 Stockholm, Sweden

We demonstrate a new and versatile method to measure, on a nanometric scale directly, the magnetostrictive properties during the magnetization process to saturation, using a modified scanning tunneling microscope (STM). Both positive and negative magnetostrictive amorphous as-quenched wires have been studied. The studied samples are *single* pieces of amorphous wires typically 125 μm in diameter and 10–15 mm long. The magnetostriction data are then correlated with the longitudinal magnetization process, measured by a conventional induction technique and by SQUID magnetometry. The longitudinal magnetization process measurements have been performed in the same wires used in the STM studies. The field dependence of the magnetostriction helps to discern the operative magnetization process in the wires. In a 12-mm-long Co-based amorphous wire we observe a continuous rotation of the magnetization from zero field to saturation. The field dependence of the magnetization is a linear process reaching a value of about 5100 G at 8 Oe applied field. The magnetostrictive process for the same wire measured with a STM shows a continuous shrinking of the samples as a function of the applied field, reaching a value of -2 0 Å for 8 Oe applied field. The obtained $\delta l/l|_{sat}$, -2.3×10^{-6}, agrees well with reported values of the saturation magnetostriction constant for this wire. In a 15-mm-long Fe-based amorphous wire we observe a more complicated field dependence of both the magnetization and the magnetostriction processes from zero-field to saturation. The longitudinal magnetization saturates at about 14000 G for 60 Oe applied field. The magnetostrictive process for the same wire measured with STM shows an elongation onset at about 1 Oe, pointing unambiguously to a 180° domain wall movement as the operative magnetization process below this field value. The field dependence of the magnetostriction saturates at about +5000 Å for 60 Oe applied field. The obtained $\delta l/l|_{sat}$, about $+3.3\times10^{-5}$, is again consistent with reported values of the saturation magnetostriction constant. Thus the STM approach to determine λ, on an Å length scale, gives us a distinct great advantage in studying the magnetization process towards saturation.

Tunable bistability from magnetostriction (abstract)

A. S. Arrott and J.-G. Lee
Simon Fraser University, Burnaby, British Columbia V5A 1S6, Canada

When a current passes along the axis of a [100] iron whisker in the presence of a field along the same axis, the magnetization in a central domain points along the field direction while the mangetization in four domains surrounding the central domain circulates about the axis, see Fig. 1. The size of the central domain grows with applied field, which overcomes the effect of the field from the current and the magnetostriction that favor the collapse of the central domain to an irreducible core. Depending on the current, the growth of the central domain can be a continuous or discontinuous process. At certain fields the energy is a double-well function of the size of the central domain, which determines the magnetization. The size of the energy barrier can be made arbitrarily small by suitable choice of the current. It is the ability to adjust the size of the barrier in such a clearly defined system that makes this an attractive experimental approach to understanding the role of fluctuations in magnetization processes. This structure has been verified using measurements of ac susceptibility.

Influence of Stoner-type excitations on the formation of magnetization and magnetic order in disordered metal-metalloid alloys

A. K. Arzhnikov, L. V. Dobysheva, and E. P. Yelsukov
Physics-Technical Institute, Kirov str. 132, Izhevsk 426001, Russia

The Rhodes–Wolfarth parameter and the ratio $T_c^{1/2}(x)/\bar{m}(x)$ have been analyzed on the basis of experimental data for disordered alloys Fe–Al, Fe–Si, Fe–P (T_c is the Curie temperature, $\bar{m}$ is the average magnetic moment, x is the concentration of non-magnetic impurity). The concentration dependences of these parameters show the possibility of considerable contribution of the Stoner excitations to the magnetic order formation. The analysis of the two-band Hubbard model shows that the Stoner excitations result in the turnover of the local magnetic moment at a certain temperature in the range of high concentration of nonmagnetic atoms.

For a long time the disordered alloys of metal–metalloid type (Fe–Al, Fe–Si, and Fe–P) have been attracting the attention of scientists. This interest is mainly due to the fact that these alloys are a good model object for studying the fundamental regularities of magnetic properties formation in disordered systems. The method of mechanical alloying makes it possible to widen the concentration range of a disordered state in these alloys.[1–5] Regularities of behavior of hyperfine field $\bar{H}$, isomeric shift $\bar{\delta}$, average magnetic moment $\bar{m}$, temperature of magnetic ordering T_c obtained in these papers,[1–5] combined with the data of other authors[6–8] and see references in Ref. 5, give the complete picture of the above characteristics behavior in the whole concentration range of magnetic order existence. Besides, the possibility of comparing the experiments on specimens obtained by different techniques, in particular, in amorphous and crystalline disordered states, has appeared. One can draw the following conclusions for the data available. The concentration dependences of $\bar{H}$, $\bar{\delta}$, $\bar{m}$, and T_c have the same qualitative peculiarities for all the above-mentioned alloys, that is, weak dependence on concentration x in the low concentration range (for Al—$x<30\%$, Si—$x<18\%$, P—$x<12\%$) changes into a sharper dependence in the range of high concentration of metalloid, and the local magnetic moments decrease with increasing the number of nonmagnetic atoms in the nearest environment.[1–4] This indicates that the main principles of magnetic moment formation in these alloys are similar. It is our opinion that the quantitative differences of concentration dependences of the alloys are dictated by different numbers of p electrons of a metalloid atom (Al—$n_p=1$, Si—$n_p=2$, P—$n_p=3$). While comparing the data for the amorphous and crystalline specimens, the conclusion can be made that the influence of topological disordering on the magnetic properties is weak, as compared to that of the compositional one.[5] A variety of models, for instance,[5–8] based on the Jaccarino–Walker model, where the average magnetic moment is defined by $\bar{m}=\Sigma_k P_k m_k$, were proposed for the phenomenological description of concentration dependences of $\bar{H}$, $\bar{\delta}$, and $\bar{m}$ of these alloys. The modification of the Jaccarino–Walker model put forward by one of the authors[1–4] provides a most successful description. This modification includes the interpolation of the dependence of the Fe magnetic moment on the number of nonmagnetic atoms in the nearest environment using the data available for ordered alloys, and the assumption that the probability of a configuration in the middle-concentration region $x_1<x<x_2$ looks like

$$P_k(x)=\sum_{n=0}^{6}\begin{bmatrix}6\\n\end{bmatrix}(1-x_{\rm rel})^{6-n}x_{\rm rel}^{n}\begin{bmatrix}8+n\\k\end{bmatrix}\times\left(1-\frac{x}{100}\right)^{8+n-k}\left(\frac{x}{100}\right)^{k},$$

where $x_{\rm rel}=(x-x_1)/(x_2-x_1)$, $x_1=25$, 15, 7 at. %, $x_2=55$, 33, 20 at. % for Fe–Al, Fe–Si, and Fe–P, respectively.

The justification of the modified Jaccarino–Walker model can be found in detail in Ref. 5. It should be mentioned that the Jaccarino–Walker models are conceptually closer to the localized models, whereas magnetism in Fe is the itinerant one.[9] This contradiction between the localized character of Jaccarino–Walker models and the itinerant magnetism of Fe has been removed after we had analyzed the disordered Hubbard model.[10] In addition, this model for the disordered alloys on the basis of the two-band Hubbard Hamiltonian proposed in Ref. 10 allowed us to explain the main qualitative regularities of the formation of the magnetic moment and isomeric shift of the magnetic atom under different impurities configurations in the ground state.

When analyzing the theoretical results, we have noted that the magnetic moment of magnetic atoms with many nonmagnetic atoms in the environment decreased drastically in magnitude, and the energy distribution of the electrons became flat, due to a strong $s-d$ hybridization. This shows the possibility of the great importance of Stoner excitations, even at low temperatures. In addition, we analyzed the experimental data for Fe–Si[2,11] for the Rhodes–Wolfarth (RW) relation M_c/M_s, where M_s is the saturation magnetic mo-

 0021-8979/94/76(10)/7032/2/$6 00 © 1994 American Institute of Physics

ment per magnetic atom and M_c is the effective moment per magnetic atom defined from the Curie constant, with the assumption of the existence of local moments (see Ref. 12, Chap. 7.1), and found that this parameter changes from 1.4 to 1.8 on changing the nonmagnetic component concentration from 0% to 28%. The large RW parameter testifies that the nature of the alloy magnetism becomes closer to "weak ferromagnetism" at high Si concentration (hereinafter this term means the magnetics with Stoner excitations[9]). Unfortunately, it is, in many cases, impossible to obtain the concentration dependence of the RW parameter because of technical difficulties of measuring the high-temperature Curie constant. In a wider concentration region, the experimental data available allow us to analyze the parameter $T_c^{1/2}(x)/\bar{m}(x)$ [T_c is the Curie temperature, $\bar{m}(x)$ is the magnetization at $T=0$]. As follows from our theoretical investigations of the Heisenberg model with nonmagnetic impurities,[13] such a parameter must decrease as the concentration tends to the percolation threshold. Contrastingly, this parameter in Fe–Al, Fe–Si, and Fe–P increases when the concentration of nonmagnetic impurities increases. As evidenced by all the above experimental estimations, the Stoner excitations may play a significant role in the formation of magnetization in these alloys at high metalloid concentration.

Finally, on the basis of the two-band Hubbard model proposed in Ref. 10, we carried out a theoretical investigation of the behavior of local magnetic moments under given configurations of the nearest environment, depending on the temperature. These calculations have been conducted in the middle-field approximation for the electron–electron interaction. A cluster of the predetermined configuration was placed in the effective medium calculated in the coherent potential approximation. The excitations of Stoner type were taken into account through the Fermi distribution, the self-consistence of the local magnetic moment being achieved at every temperature. As a result, we obtained the following. At low concentrations the influence of Stoner excitations becomes noticeable only at temperatures of $kT/W \simeq 0.2$–0.25 (W is the width of the d band), which corresponds to the usual results for "strong" ferromagnets of the Fe type (see Ref. 9). At concentrations near the critical one, the situation radically alters, and the Stoner excitations result in essential changes of magnetization, even at $kT/W \simeq 0.015$. For instance, at concentrations of the order of 0.6, there exists only one solution in the ground state for the configuration with four nonmagnetic atoms in the nearest environment, with a magnetic moment being opposed to the total magnetization (see Ref. 10). Along with this solution, the second one with a positively directed magnetic moment appears at $kT/W \simeq 0.01$, the energy of it being higher than that of the first solution. At temperature $kT/W \simeq 0.02$ the energies of these two states become equal, and further, when temperature increases the second state becomes preferable in energy. So at these temperatures, the local magnetic moment has to change from negative to positive. That is, the Stoner excitations cause the increase of the average magnetic moment with an elevation of temperature. Such changes of the magnetic moment due to the Stoner excitations can be an alternative to the explanation of the magnetization behavior by the excitations of a spin glass state. It is worth noting that although there is a latent antiferromagnetic ordering of the magnetic moments in our model, it is similar to Mattis' glasses ordering, and not to the spin glasses one.

So, as experimental and theoretical works show, in the range of high concentrations of nonmagnetic impurities in the Fe–Si, Fe–Al, and Fe–P alloys, the band character of the magnetism must fully manifest itself in the temperature dependences, and description of these alloys on the basis of the localized models of Heisenberg and Ising seems to be unjustified.

Measurements of the χ') part of the ac magnetic susceptibility have been performed on two polycrystalline Gd_2CuO_4 samples sintered at different temperatures, 850 °C and 1080 °C in the temperature range $10<T(K)<300$. Two well-defined maxima have been observed in the temperature dependence of χ'. One, located at about 20 K, that is frequency independent. The second is at about 280 K for the sample annealed at 1080 °C, and it is frequency independent. Instead, for the sample annealed at 850 °C the maximum appears at about 210 K, and it is frequency dependent. These results suggest the existence of magnetic domains, with their coherence lengths being a function of the thermal treatment.

I. INTRODUCTION

Rare earth cuprates R_2CuO_4 are characterized by the presence of long-range-order antiferromagnetism (AF) associated with the ordering of the magnetic moments of the Cu^{+2} ions. This AF ordering presents a three-dimensional/two-dimensional (3D/2D) transition at a temperature (T_N) between 250–280 K. The study of the magnetic properties of these compounds has initially led to their classification into two groups:[1] the first one with R=Pr, Nd, Sm, Eu, and the second with R=Gd and heavier rare earths. Both groups crystallize in the tetragonal T' structure, but, in the second group, a distortion of the oxygen in the CuO_2 planes in a direction perpendicular to the Cu–O–Cu bond[2,3] leads to an antisymmetric superexchange interaction that generates a weak ferromagnetic behavior.[4,5] Whereas for the former group superconductivity (SC) is achieved with Th or Ce doping,[6] for the latter superconductivity has not been observed.[7] The exclusion of weak ferromagnetism (WF) and SC has been recognized by several authors.[1]

A subdivision in the second group, revealing differences between Gd_2CuO_4 and the R_2CuO_4 (R=Tb, Dy, Ho, Er, and Tm) obtained at high pressure[8] (PO) has been suggested.[9] A difference is encountered in the temperature dependence of the ac magnetic susceptibility,[9] where Gd_2CuO_4 presents a double peak structure in the real part of the susceptibility at low temperatures, from $T\approx1$–20 K; while for the PO compounds only one peak, associated to the ordering of the R ions, appears in that range. The explanation of this difference has been sought in comparison between the R–R and R–Cu sublattice interactions. Differences have also been reported in the dynamic behavior of these compounds.[10] The mechanism leading to the observed dynamical behavior remains unclear, although spin-glass-like effects have been claimed.[10]

The aim of the present work is to perform a detailed study of the ac magnetic susceptibility of polycrystalline Gd_2CuO_4 in the temperature range $10<T(K)<300$. A comparison with ac magnetic susceptibility measurements of other weak ferromagnets of the R_2CuO_4 series is also presented.

II. EXPERIMENTAL TECHNIQUES

Gd_2O_3 and CuO oxides were used as starting materials for the ceramic synthesis of Gd_2CuO_4. Two methods were used to obtain the samples: (a) Stoichiometric amounts of the starting materials were milled for several hours and thermal treatments at 850 °C, with frequent intermediate millings were subsequently carried out. Around 400 h were required in order to obtain the pure Gd_2CuO_4 phase. We call this sample, sample I. (b) In the second method, the starting materials were sintered at 950 °C for 12 h. The product was milled again and resintered at 1000 °C for 20 h. Finally, it was sintered at 1080 °C for 24 h and slow cooled. The sample thus obtained is called sample II.

The structural characterization of the samples was performed by means of x-ray diffraction using a Philips PW-1710 diffractometer with Cu anode ($CuK_{\alpha1}$ radiation, $\lambda=1.540\,60$ A). The x-ray patterns showed a single phase with the same tetragonal structure for both samples. The analytic characterization was derived using inductively coupled plasma atomic emission spectroscopy (ICP-AES) with Ar plasma ICP (Perkin-Elmer 5000). The dc magnetic measurements were performed using a SQUID magnetometer (Quantum Design) in the $4<T(K)<300$ temperature range. The real and imaginary parts χ' and χ'', of the external complex ac susceptibility were measured during warming from $T=13$–300 K using a system with a concentric assembly consisting of a primary solenoid and two oppositely wound

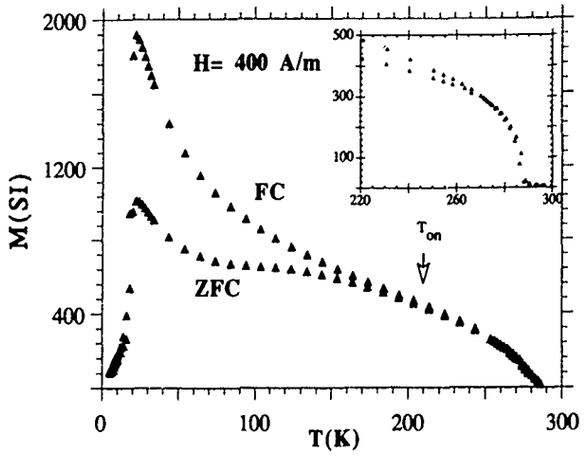

FIG. 1. FC and ZFC dc magnetization of the Gd_2CuO_4 sample I vs temperature, measured with an applied field of H_{appl}=400 A/m. The inset shows the dc magnetization for sample II.

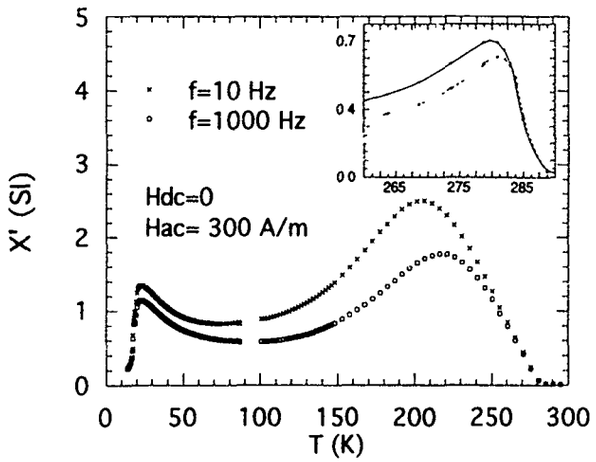

FIG. 2. The real part of the ac susceptibility, χ' of sample I, measured at frequencies of 10 and 1000 Hz in an ac magnetic field of H_{ac}=300 A/m. The inset shows the curve for sample II in the high temperature range.

sensing coils connected in series. A phase-sensitive detector is used to measure the output voltage that is proportional to the sample susceptibility. High sensitivity is obtained by moving the sample between the two sensing coils with high precision. The calibration was performed using a $Gd_2(SO_4)_3 \cdot 8H_20$ standard with the same shape and size as the investigated samples. Demagnetizing effects have been taken into account in the calculation of the internal susceptibility. For each run of measurements, the ac field was applied with a fixed amplitude of H_{ac}=300 A/m and fixed frequencies f, ranging from 5 to 1000 Hz. A dc field, H_{dc} from 0 to 800 A/m, was generated by applying a dc current to the primary coil. The temperature of the samples was controlled with an accuracy of about 0.1 K.

III. EXPERIMENTAL RESULTS

In Fig. 1, we display dc magnetization measurements for both Gd_2CuO_4 samples when they were (a) zero field cooled (ZFC) from 300 to 4 K (H_{cool}<80 A/m), and subsequently measured at increasing temperatures with an applied field, H_{appl}=400 A/m; and (b) field cooled (FC), i.e., measured at an applied field while cooling down from 300 K at $H_{cool}=H_{appl}$=400 A/m. The difference between the ZFC and FC curves indicates the onset of irreversibility for this field at a temperature $T_{irr}\approx$210 K for sample I and $T_{irr}\approx$280 K for sample II.

In Fig. 2, we show the temperature dependence of χ' at two different frequencies. We observe for both samples, two well-defined peaks. For sample I, one peak is centered at $\approx$210 K (T_{M1}) and the other at $\approx$20 K (T_{M2}). The high temperature peak is frequency dependent (it shifts to a higher temperature with an increasing frequency, as shown in Fig. 3). Instead, the low temperature peak is frequency independent. For sample II, the position and behavior of T_{M2} is similar to sample I. But T_{M1} is found at $\approx$280 K, and it is frequency independent.

Figure 4 shows the temperature dependence of χ' for sample I measured at the same ac field (H_{ac}) for different superposed dc fields (H_{dc}). We observe that the amplitude of the 210 K maximum decreases with increasing field and disappears for a dc field of about H_{dc}=800 A/m. The maximum onset temperature ($\approx$280 K) and the position of the maximum remains constant. For the 20 K peak, the dependence on the dc field is much weaker. It shifts slightly toward lower temperatures and decreases in amplitude with increasing field.

IV. DISCUSSION

The existence of WF in the R_2CuO_4 series is accompanied by the presence of irreversibility effects.[10,11] Differences are observed in the irreversible behavior of Gd_2CuO_4, depending on the thermal treatment. For the sample annealed at high temperature, sample II, the irreversibility appears at a temperature of the order of the AF 3D/2D ordering of the Cu^{+2} ions, $T_N\approx$270 K. Instead, for the sample annealed at a low temperature, sample I, T_{irr} and the temperature of the maxima of the real and imaginary parts of the susceptibility

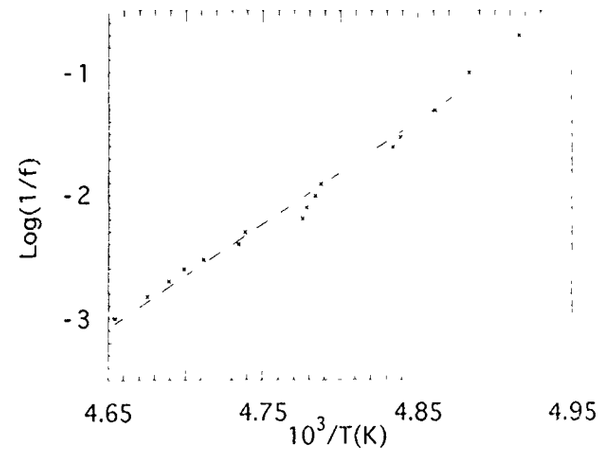

FIG. 3. Frequency dependence of the high temperature peak T_{M1} for sample I

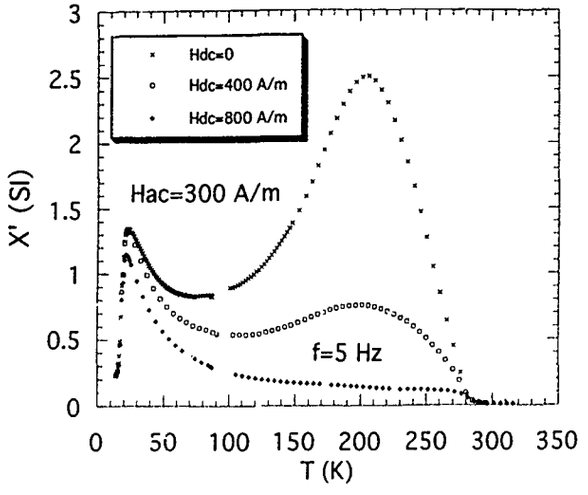

FIG. 4. Temperature dependence of χ' of sample I measured at the same ac magnetic field (H_{ac}=300 A/m) for different superposed dc fields (H_{dc}).

are located at $T \approx 210$ K, which is much lower than T_N. Another difference is that for sample I the position of the high temperature χ' maximum is frequency dependent. This dependence is not observed for sample II, as in the case of other weak ferromagnetic compounds treated at high temperature.[1]

The low temperature peak observed for both samples may be interpreted as due to a phase transition. Below this temperature, both the WF and the dynamic effects disappear, as seen in Fig. 5. This figure shows several isotherms of χ' versus the frequency. As we decrease the temperature below 20 K, the isotherms become frequency independent. The origin of this transition has been associated to the competition between the Gd–Gd and Gd–Cu interactions.[3]

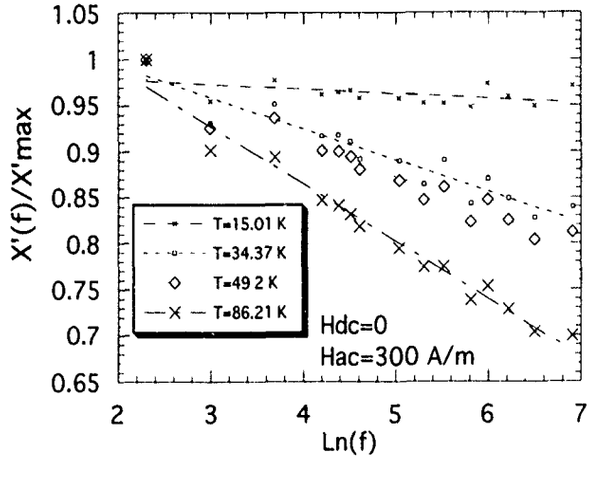

FIG. 5 χ' vs frequency at selected temperatures.

To analyze the frequency dependence of the high temperature maximum, we have plotted the data in an Arrhenius law form (Fig. 3). In the examined temperature range the relationship is linear. We have found that the Arrhenius law, predicted for independent fine particles or isolated clusters does not describe the observed dynamic properties, as a non-physical value was obtained for the pre-exponential factor τ_0 ($\tau_0 \approx 10^{-50}$ s). The observed frequency dependence could be associated to the existence of different magnetic domains (or large clusters). The domain size should be related to the coherence length of the oxygen distortion. This coherence length seems to be strongly dependent on the thermal treatment.

Finally, we discuss the effect of the superposition of a dc field on the ac measurements. The broadening of the 210 K maximum, and the decrease of its amplitude with increasing H_{dc} shows the effect of the field on the resulting WF and on the dynamical behavior of the magnetic domains. The small shift of the 20 K maximum to lower temperatures with the superposition of a dc field is consistent with the H–T phase diagram for Gd_2CuO_4 presented in Ref. 3.

J. G. Zhao
Institute of Physics, Academia Sinica, 100080 Beijing, People's Republic of China

We present studies on both the electronic and magnetic properties of $LaCo_{13}$ and $La(Fe_xAl_{1-x})_{13}$ intermetallic compounds by cluster model calculations within the scheme of density-functional theory. The equilibrium structures of the isolated and embedded clusters, obtained by minimizing the total binding energy, are in good agreement with available experimental data and other theoretical results. The relative stability and formation of $LaCo_{13}$ and $La(Fe_xAl_{1-x})_{13}$ phases have been successfully explained. Interesting changes of magnetic properties in an Al doped Fe_{13} cluster have been obtained. The possible effect of Al on the magnetic phase diagram of $La(Fe_xAl_{1-x})_{13}$ is discussed.

The cubic $NaZn_{13}$-type alloys have long been the subject of much research. Recently, the successful fabrication of $LaCo_{13}$, $La(Fe_xAl_{1-x})_{13}$ alloys have enriched this family and attracted much experimental and theoretical interest.[1] Their structures are based on a faced-centered cubic lattice with the space group O_{h6}–F_{m3c} and eight molecular formulas in the unit cell. La atoms (e.g., for $LaCo_{13}$) are at the body centered positions. There are two nonequivalent positions for Co atoms. One of the important features of this structure is that Co_I is surrounded by 12 Co_{II} at the vertices of a regular icosahedron, and the La atom is at the center of a snub cube, with Co_{II} atoms at its 24 vertexes. It is well known that the icosahedral structures are very stable for many kinds of 13-atom clusters. The relative stability and electronic structure of the local icosahedral cluster may contribute to the formation of the characteristic $NaZn_{13}$-type structure. In experiments, it has been found that $LaCo_{13}$ alloy is stable, while the $LaFe_{13}$ alloys is not stable, but it can be stabilized by suitable doping with Al atoms. Many experiments show that $La(Fe_xAl_{1-x})_{13}$ alloys are only stable with the x range between 0.46 and 0.92.[2] Neutron diffraction experiments suggest that Fe and Al atoms not be randomly distributed in the alloys, the Co_I sites be completely occupied by Fe, Al atoms substitute Fe atoms in the Co_{II} sites.[3] The doping of Al in the icosahedral Fe_{13} cluster changes both relative stability and electronic structures of the local unit structure, which consequently favors the formation of $NaZn_{13}$-type alloys. The doping of Al also changes the magnetic properties of La–Fe alloys. The measurement of susceptibility reveals that $La(Fe_xAl_{1-x})_{13}$ alloys exhibit a unique magnetic diagram varying from the micromagnetic state to the ferromagnetic state and the antiferromagnetic state, with the increase of the Fe concentrations. The measurement of electrical resistivity and magnetization also suggest that local electronic and magnetic properties have played an important role in the properties of those alloys.[4] It is natural to ask why $LaCo_{13}$ alloys are stable, while $LaFe_{13}$ is only stable with some doping of Al, and also why the variant doping changes the magnetic and electronic properties? These problems are not been fully understood. In this paper, based on a cluster model, we have calculated the electronic structures and the total binding energies of $LaCo_{13}$ and $La(Fe_xAl_{1-x})_{13}$ alloys, trying to understand the relative stability of these alloys from a local structure point of view, and identify the role played by Al atoms in the $La(Fe_xAl_{1-x})_{13}$ alloys. We have used the icosahedral Co_{13}, Fe_{13}, and $Fe_{12}Al$ clusters to study the local properties of $LaCo_{13}$ and $La(Fe_xAl_{1-x})_{13}$ alloys. To take into account the effects of the crystal field, we also have studied the clusters embedded in the crystal. The calculations are performed using the density functional theory with a local spin density approximation.[5] The discrete variational method has been used to solve the Kohn–Sham equation.[6] In our calculations, the basis sets are the numerical atomic valence orbitals of $3d4s$ for Fe and Co atoms, and $3s3p$ for the Al atom, we have found that when including the more diffusive orbitals in the basis set, there were very small effects on equilibrium atomic distances and electronic structures. The inner orbitals are kept frozen in all the calculations. Group theory has been adopted to classify the molecular orbitals and consequently simplify the calculations. The equilibrium structures of all the calculated clusters are obtained by minimizing the total binding energies for several center to vertex distances, keeping the corresponding symmetry. The binding energy is defined by $E_b = E_{tot} - E_{ref}$, where E_{tot} is the total energy of the cluster and E_{ref} is the sum of the total energies of individual atoms. We have used the Mulliken population to get the occupation numbers for atomic orbitals.[7] The magnetic moments for each atom are the difference of electrons between spin-up and spin-down states.

In Table I, we have presented the calculated magnetic moments and the theoretical equilibrium distances from center to vertex for Co_{13}, Fe_{13}, and $Fe_{12}Al$ clusters, but for the embedded clusters, we have used the experimental atomic distances in the corresponding bulk phases. From Table I, we can see that the equilibrium distances of Co_{13} and Fe_{13} are almost the same, the small difference may come from the difference of atomic sizes for Co and Fe atoms. Actually, the

TABLE I. Some properties of all the calculated clusters. μ_c is the magnetic moments of Co_I sites. μ is the average magnetic moments per the Fe or Co atom of a cluster.

	Isolated clusters			Embedded clusters		
	Co_{13}	Fe_{13}	$Fe_{12}Al$	Co_{13}	Fe_{13}	$Fe_{12}Al$
d_0 (a.u.)	4.65	4.63	4.73	4.64	4.57	4.59
$\mu_c(\mu_B)$	2.38	3.25	2.97	2.94	3.85	4.20
$\mu(\mu_B)$	2.38	3.38	2.99	2.83	3.83	4.20

atomic size effects on the lattice constants can also be observed in $LaCo_{13}$ and $LaFe_{13}$ alloys, the distance between Co_I and Co_{II} in $LaCo_{13}$ is 4.64 a.u., similarly, the distance between Fe_I and Fe_{II} in $LaFe_{13}$ extrapolated from experimental data[2] is 4.57 a.u. The fact that the theoretical equilibrium distance for the icosahedral Co_{13} and Fe_{13} are very close to the experimental value in the LaM_{13} (M=Co,Fe) bulk phases suggest that the local icosahedral cluster will not be affected very much by the crystal environments. When substituting Fe with Al, we found an increase of equilibrium distance, which is in agreement with the experimental fact that the lattice constant increases with the increase of Al concentrations. This phenomenon can be easily understood, because the Al atoms have more diffusive electronic orbitals and hence a large atomic size. In Fig. 1, we show the calculated binding energies for all the clusters at the equilibrium center to vertex distance d_0. We obtained about ~45 eV binding energy for the Fe_{13} cluster, which is also in agreement with other theoretical calculations,[8] and the Co_{13} has about ~30 eV binding energy. On doping Al in the Fe_{13}, as shown in the figure, we found the binding energy of $Fe_{12}Al$ shifted up a little bit. We can expect that the binding energy will increase if the shifting Al atom outward deviated from a perfect icosahedron. In Fig. 2, we have plotted the eigenvalue spectra for all the calculated clusters. In the Co_{13} cluster, we obtained a fourfold degenerate G_g molecular orbital for the highest occupied state (HOMO), but the HOMO is not completely occupied and there are three electron deficiencies, so, in principle, the isolated icosahedral Co_{13} will not be stable, at least Jahn–Teller distortion will lower the total energy. But why are the $LaCo_{13}$ alloys with an icosahedral structural unit stable? This striking question can probably be understood as following. It is well known that the La atom has a strong tendency to lose three valence electrons. If La atom support Co_{13} with three electrons to fill the deficiency in HOMO, it makes the icosahedral Co_{13} stable with a closed electron shell. The large ion core of La atoms fills the space among icosahedral Co_{13} clusters. In this way, the icosahedral Co_{13} can be considered as superatoms, the complicated $LaCo_{13}$ alloys can be composed of a *superatom* Co_{13} and La atom. In fact, the idea of superatom that had been used successfully to explain the stability of icosahedral quasicrystals[9] is also applicable to many other systems. We have checked other Zn based AB_{13} alloys, we found the same explanation can be used. In the similar way, we can understand the stability of $LaFe_{13}$ alloys. In the Fe_{13} cluster, we obtain a five-fold degenerate H_g molecular orbital for the HOMO, but with only one electron in this orbital, and there is four-electron deficiency. So even though the La atom offers three electrons, the HOMO still cannot be completely filled like in Co_{13}, which means that the Fe_{13} cluster in

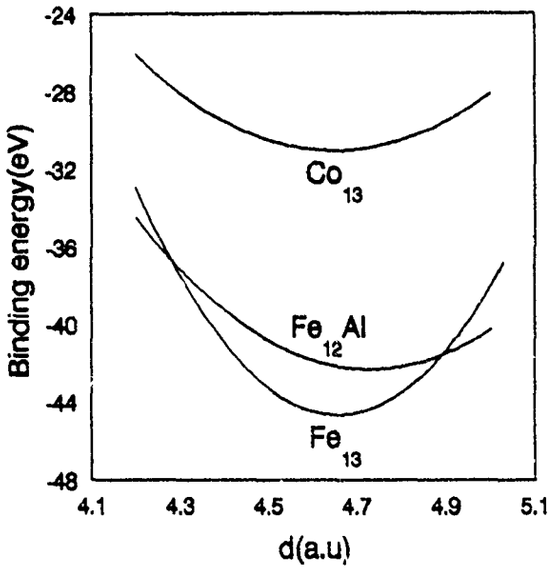

FIG. 1. The binding energy curves vs radial bond distance for Co_{13}, $Fe_{12}Al$, and $Fe_{11}Al_2$ clusters.

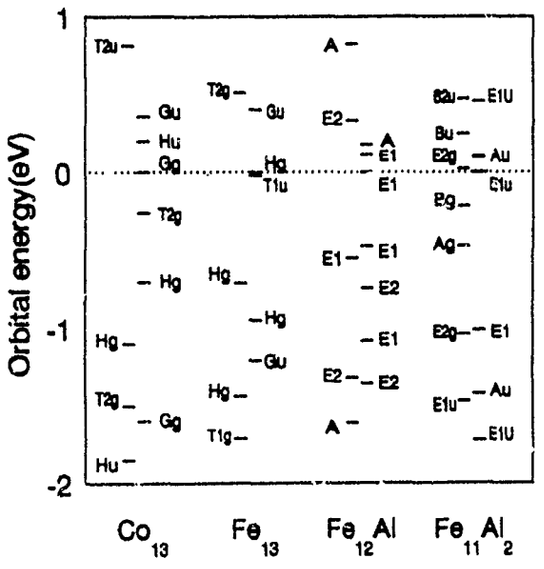

FIG. 2 Energy spectra c .he isolated Co_{13}, $Fe_{12}Al$, and $Fe_{11}Al_2$ clusters.

$LaFe_{13}$ alloy cannot be stable. All these results are consistent with experimental facts.[1,2] To see the influence of substituting Fe by Al on the stability and properties of $La(Fe_xAl_{1-x})_{13}$ alloys, we have studied the $Fe_{12}Al$ and $Fe_{11}Al_2$ clusters, which represent the alloys at the different region of a magnetic phase diagram. The experiments have already found that the Al atom did not occupy the center of the icosahedron,[3] so we chose $Fe_{12}Al$, with D_5 symmetry. From the eigenspectrum in Fig. 2, we can see the HOMO is two-fold degenerate, with only one electron in it, the two-fold degenerate lowest unoccupied molecular orbital (LUMO) is also very close to the HOMO, three electrons provided by the La atom can fill the one electron deficiency in HOMO and also fill the two-fold degenerate LUMO; consequently, the $Fe_{12}Al$ has a closed electron shell and becomes stable, which might be the reason why the experiment found the $Fe_{12}Al$ alloys stable. In a similar way, we can expect that the $Fe_{11}Al_2$ would be stable in the $La(Fe_xAl_{1-x})_{13}$ alloys.

In Table I, we have presented the magnetic moment for all calculated clusters, we have obtained the Co atom with $2.38\mu_B$ magnetic moments, which is in good agreement with other theoretical and experimental results.[10,11] We have also obtained a large average magnetic moment ($3.38\mu_B$) for the free icosahedral Fe_{13} clusters, and observed the magnetic moments for the atom at the center of the icosahedron are parallel to the magnetic moments for the atoms at the vertexes, which suggest that the ground state of the Fe_{13} cluster be ferromagnetic, in agreement with other theoretical calculations.[12] When doping with Al, we find the cluster expands and the magnetic moments decrease. This occurrence of decrease of the magnetic moments can be attributed to that more and more iron atoms will lose their magnetic moments when Fe concentration decreases. This is confirmed by our studies on the $Fe_{11}Al_2$ clusters with D_{5d} symmetry; we have found the magnetic moments for Fe atoms in $Fe_{11}Al_2$ are even smaller than that in $Fe_{12}Al$ cluster. Hence, based on the results of the present cluster model calculations, it can be expected to get Pauli paramagnetism when decreasing the iron concentration and consequently decreasing the magnetic interaction, which is in agreement with the complicated experimental magnetic phase diagram of $La(Fe_xAl_{1-x})_{13}$ alloys. In all the embedded clusters, we find a very similar eigenvalue spectra to the isolated clusters discussed above, so the same idea can be applied to stability of the embedded clusters, which have included the influence of the crystal field generated by 824 atoms. But we observed a small increase of magnetic moments with respect to the isolated clusters.

In summary, the electronic and magnetic properties of the four $NaZn_{13}$-type compounds, $LaCo_{13}$, $LaFe_{13}$, $LaFe_{12}Al$, and $LaFe_{11}Al_2$ have been studied by modeling those alloys by cluster on the basis of density functional theory. We found the relative stability as well as electronic structure of $NaZn_{13}$-type alloys can be explained according to its local icosahedral structural units. The main role of Al is to modify local electronic structure; this may facilitate the formation of the stable $NaZn_{13}$-type structure for the La–Fe alloys. In addition, the change of local magnetic properties with the change of Al concentrations bears resemblance to that of the alloys.

By means of neutron powder diffraction, we find that UCoGa crystallizes in the hexagonal ZrNiAl structure and orders ferromagnetically at low temperatures with magnetic moments stacked along the c axis. The magnetic-ordering temperature is reflected in anomalies in the temperature dependencies of the electrical resistivity and the specific heat at $T_C = 47$ K. Furthermore, the strong anisotropy in the electrical resistivity for $i \| c$ and $i \perp c$ indicates a significant contribution of the magnetic anisotropy to the electrical resistivity.

I. INTRODUCTION

UCoGa belongs to the large group of UTX compounds (T=transition metal, X=p-elec[illegible]metal), and is reported to crystallize in the hexagonal Zr [illegible]ucture.[1] Previous bulk magnetic investigations[2–4] revealed a magnetic order at about 47 K, but the results were inconclusive regarding whether the ground state is ferro- or antiferromagnetic.[4] The purpose of the present contribution is to determine the structural parameters and to clarify the type of ground state, as well as to investigate the bulk transport and thermal properties of single-crystalline UCoGa.

II. EXPERIMENTAL

For the present investigations, we have used two kinds of samples: polycrystalline material and a small single crystal. The polycrystal, which has been used in the neutron-diffraction experiments, was prepared by arc-melting appropriate amounts of the constituting elements with a purity of at least 99.99%. The small single crystal is the same as was used in a previous investigation.[4] Neither the polycrystal nor the single crystal have been annealed.

For neutron-diffraction experiments, the polycrystal was ground and enclosed with helium gas in a sealed vanadium tube, which was mounted on the cold finger of a closed-cycle refrigerator. This setup was installed in the High Intensity Powder Diffractometer (HIPD) at the Los Alamos spallation pulsed neutron source LANSCE. Data have been taken on six detector banks ($2\Theta = \pm 40, \pm 90, \pm 153$) at 60, 35, and 10 K. The diffraction patterns were analyzed using the Rietveld refinement program GSAS.[5] The magnetic intensities were also analyzed by extracting integrated intensities for individual peaks and fitting to models for the magnetic structure.

The temperature dependence of the electrical resistivity was measured between 4.2 and 300 K, with the standard four-point ac method on two small bar-shaped single crystals of typical size $0.5 \times 0.5 \times 2$ mm^3, where the largest distance coincides with the c axis for the first sample and is perpendicular to the c axis for the second one. The large error in the determination of the geometrical factor makes a reliable estimate of the absolute resistivity values impossible.

At 4.2 K, the field dependence of the electrical resistivity in magnetic fields up to 35 T has been measured in the Amsterdam High-Field Installation, with an $i \| B \| c$ axis.

The temperature dependence of the specific heat has been measured between 4.2 and 100 K, making use of both standard adiabatic and the relaxation-time method.

III. CRYSTAL AND MAGNETIC STRUCTURE

UCoGa crystallizes in the hexagonal ZrNiAl structure (space group: P$\bar{6}$2m). The structural parameters of UCoGa have been derived by neutron powder diffraction at 60 K, and the results of the refinement are listed in Table I. The absence of any unindexed reflection in the parent phase suggests that there is no impurity in the present sample. However, the reduced χ^2 drops by 5% when a slightly lower atomic fraction of Co and slightly higher fraction of Ga (of the order of 1% in both cases) are assumed. This result indicates a small deviation from the exact 1:1:1 stoichiometry. For UCoGa, the nearest interuranium distance d_{U-U} is found

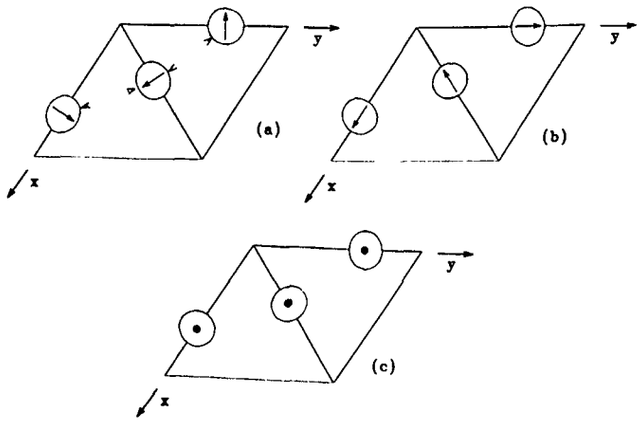

FIG. 1. The Shubnikov magnetic subgroup of P$\bar{6}$2m. In (a), the uranium moments are perpendicular to the mirror planes, while in (b) and (c), the moments are parallel to the mirror planes. Note that, in the models (a) and (b), the moments are located within the hexagonal basal plane, while in (c) they are ferromagnetically coupled along the c axis. For clarity, only uranium atoms are shown. The dashed lines with arrows indicate the nearest uranium–uranium links.

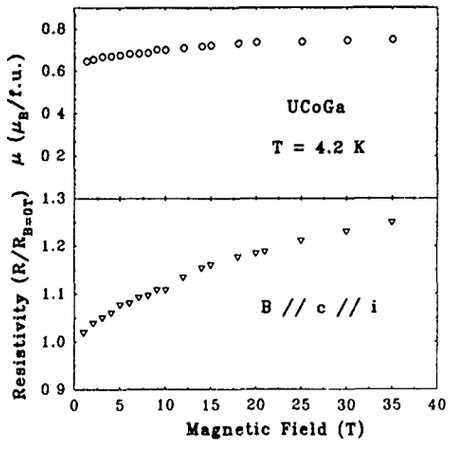

FIG. 2. Temperature dependence of the electrical resistivity of UCoGa for the $i\|c$ axis and $i\perp c$ axis normalized to the values at 300 K. In the inset, the low temperature detail for the $i\|c$ axis is shown in the representation $\rho/\rho_{300\text{ K}}$ vs T^2.

within the hexagonal basal plane (see Fig. 1), and is determined by $d_{U-U}=a\sqrt{(3x^2-3x+1)}$, where a is the lattice parameter and x is the U position parameter.

In order to clarify the magnetic structure, we have performed neutron-diffraction experiments at 35 and 10 K, well below the magnetic ordering temperature indicated by bulk magnetization results.[2–4] We do not observe any additional purely magnetic reflections at these temperatures, but an additional magnetic contribution to the nuclear reflections is found. This indicates that the magnetic unit cell is the same as the nuclear one, but antiferromagnetism is still possible in this structure. Possible magnetic structures have been derived using magnetic space-group analysis. U atoms in the unit cell lie in the mirror planes at $x=0$, $y=0$, and $x=y$ (note that x and y are at an angle of 120°). The moment corresponding to U in a certain mirror plane must be perpendicular or parallel to that mirror plane. The Shubnikov magnetic subgroups of P$\bar{6}$2m are shown in Fig. 1. Clearly, there are two antiferromagnetic noncollinear structures with moments in the basal plane, and only one ferromagnetic (collinear) model with U moments along the c direction. The fact that we do not observe any $00l$ magnetic contribution does not mean that the magnetic structure must be ferromagnetic, since the two noncollinear models also have no $00l$ magnetic contributions. This is easily understood, since the net moments in the $00l$ basal plane are zero for both noncollinear structures.

The integrated intensities have been corrected for the Lorentz factor[6] and for absorption. We find a significant magnetic contribution to the 110 reflection, which excludes structure 2(b), as this gives no intensity to this reflection. This is easily understood, since the net moments in the $hh0$ plane are perpendicular to that plane, which, in turn, gives zero magnetic contribution through the expression of $\sin\eta$, where η is the angle between the magnetic moment and the reciprocal lattice vector (in this case, $\eta=0$). On the other hand, both structures, 2(a) and 2(c), are possible and the lower reduced χ^2 of the ±90 detector banks suggests structure 2(c), the ferromagnetic one, to be more likely. However, the difference is only marginal, and, in fact, if the results obtained on the ±40 and ±153 detector banks are included into the refinement, structure 2(a) is slightly more likely. However, due to inconsistencies in the magnetic appearance in the + and − detector banks, which are less pronounced in the ±90 banks, we believe structure 2(c) to be the correct one, which is corroborated by the magnetization results. For the ferromagnetic structure 2(c), we deduce U magnetic moments of $0.74\pm0.03\mu_B$ per atom, which is in good agreement with the value of $0.78\mu_B$/f.u. obtained from the high-field magnetization.[4] Note that the Co moment is zero to within an experimental error of a $\pm0.1\mu_B$/atom. Also note that model 2(a) yields much larger U magnetic moments of about $1.04\pm0.04\mu_B$ per atom.

IV. TRANSPORT AND THERMAL PROPERTIES

The onset of magnetic ordering at $T_C=47$ K is reflected by a maximum in the temperature derivative of the electrical resistivity at this temperature (see Fig. 2) for both the $i\|c$ axis and $i\perp c$ axis. However, while for the $i\|c$ axis an appreciable reduction of the electrical resistivity with decreasing temperature is found, we observe an almost flat resistivity behavior for the $i\perp c$ axis. The observed strong anisotropy in the resistivity correlates well with the magnetic anisotropy found in bulk magnetization measurements. At 300 K, very rough estimates of resistivities yield values around 150 $\mu\Omega$ cm for the $i\|c$ axis, while twice as large values for the $i\perp c$ axis are found. Below 40 K, the electrical resistivity follow a quadratic temperature dependence for both orientations, which is shown for the $i\|c$ axis in the inset of Fig. 2. For UCoGa, we may roughly estimate the prefactors A to be about 0.216 and 0.138 $\mu\Omega$ cm/K^2 for the $i\|c$ axis and $i\perp c$ axis, respectively.

For this compound, we find at 4.2 K (Fig. 3) for the $i\|B\|c$ axis an increase of the electrical resistivity with an

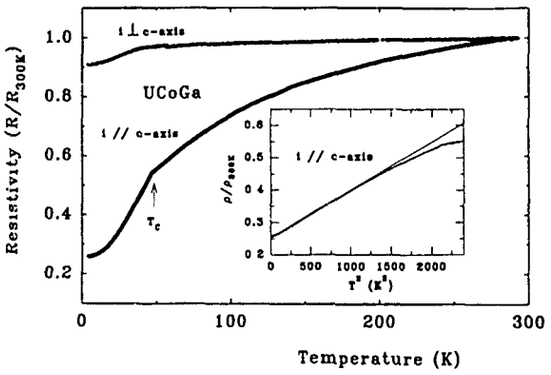

FIG 3. Field dependence of the electrical resistivity of UCoGa at 4.2 K in the configuration $i \| B \| c$ axis.

increasing magnetic field, which is in contrast to the large reduction of the electrical resistivity in the isostructural antiferromagnetic UTX compounds upon the application of sufficiently high magnetic fields.[7] The different behavior of UCoGa may be taken as a further support for a ferromagnetic ground state of this compound. At the highest fields applied, we observe a slight saturation tendency. In general, UCoGa reflects a more "normal" and expected magnetoresistance behavior, however, the total increase of the resistivity (about 27% in 35 T) is surprisingly large.

As can be seen in Fig. 4, the magnetic ordering of UCoGa is reflected in the specific heat by a maximum at T_C=47 K. After substraction of a phonon contribution determined by a Debye function with Θ_D=195 K, the magnetic entropy connected with ordering is considerably lower than

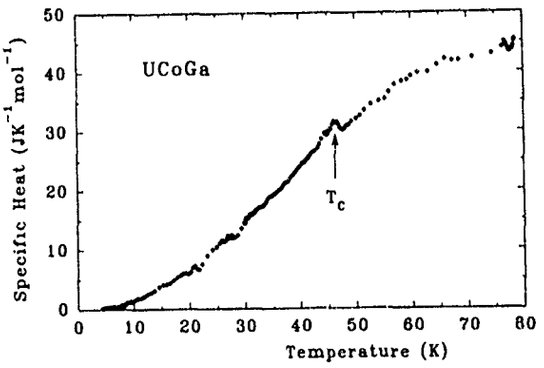

FIG. 4. Temperature dependence of the specific heat of UCoGa

R ln 9 or R ln 10, expected for the localized f^2 or f^3 configuration, respectively.

By linear extrapolation of C_p/T vs T^2 to T=0 K, we derived the coefficient γ of the electronic contribution to the specific heat, to be about 48 mJ/mol K^2.

V. CONCLUSIONS

UCoGa, which crystallizes in the hexagonal ZrNiAl structure, orders ferromagnetically below T_C=47 K with ordered $5f$ moments of about $0.74\mu_B$ stacked along the c axis. The rather low value of the ordered moments, which amounts to only half the values found in isostructural UNiX compounds,[9] confirms the expected trends arising from $5f$–d hybridization,[10] and points to a larger delocalization of the $5f$ electrons in UCoGa. For UCoGa, a significant anisotropy in the temperature dependence of the electrical resistivity has been found. Strongly anisotropic transport properties have also been detected in other UTX compounds,[11] which suggests that they are caused by the general anisotropy due to the crystal structure and the Fermi-surface anisotropy.

The fully self-consistent discrete variational method within the local-spin-density framework has been employed to obtain the electronic structure and magnetic moments of the Mn-containing cubic Laves phase pseudobinary compound of YFe_2. The calculated results show that the substitution of Mn atoms on Fe sites weakens the ferromagnetism of this compound. The magnetic moments on distinct atomic sites were derived from the calculation. We found that when the Fe atom has one Mn atom in its nearest neighbor sites, its magnetic moment decreases rapidly, while the Mn moment is $0.71\mu_B$, parallel to the Fe moment. Based upon our results, the various experimental data have been satisfactorily explained.

I. INTRODUCTION

The cubic Laves phase pseudobinary compound $Y(Fe_{1-x}Mn_x)_2$ is a puzzling system. Quite a few attempts have been made to establish its magnetic properties.[1–7] As an antiferromagnet YMn_2 with Mn magnetic moment $2.7\mu_B$,[8] the ferromagnet YFe_2 can form complete solid solutions with it, while sustaining the cubic Laves phase structure.[9] Magnetization measurements[4] and Mössbauer data[7] show the consistent result that $Y(Fe_{1-x}Mn_x)_2$ keeps ferromagnetic until the breakdown of the magnetic order in $x=0.7$. As to the magnetic moments of Fe and Mn atoms in this pseudobinary, however, contrary results have been reported. Schaafsma *et al.*[7] suggested from Mössbauer experiments that Mn appear to carry either less than $0.1\mu_B$ or no magnetic moment at all; from the NMR spectra of ^{89}Y, Nagai *et al.*[5,6] made conclusions that Fe moments are hardly changed, and there are two kinds of Mn moments: one is antiparallel to the Fe moments with about $0.6\mu_B$ and the other is parallel to the Fe moments with about $2.8\mu_B$; While Besnus *et al.*[4] showed from magnetization, diffuse neutron scattering, Mössbauer measurements, and NMR studies that Mn atoms possess magnetic moments, which are ferromagnetically coupled with Fe moments, and that the mean Fe moments decrease strongly with increasing Mn concentration, while the Mn moments appear to be less concentration dependent.

From the theoretical point of view, the problem of the pseudobinary compound $Y(Fe_{1-x}Mn_x)_2$ has been put aside yet by theorists, due to its much more complex magnetic behavior. In this paper we present calculations of charge, spin, and density of states (DOS) for the Mn-containing pseudobinary compound of $Y(Fe_{1-x}Mn_x)_2$ using the well-developed discrete variational method within the local-spin-density framework. For transition metals and intermetallic compounds, it is now well recognized that the local magnetic properties and electronic structures are mostly determined by the nature of atoms involved and the local environments of these atoms. So, several embedded clusters are chosen to simulate the local environments of atoms in the Mn-substituted YFe_2 compound, and spin-polarized calculations on these clusters are performed to study the magnetic behavior of the Mn-containing pseudobinary compound of YFe_2. The computational procedure has been documented in detail elsewhere.[10]

II. RESULTS AND DISCUSSION

The cubic Laves phase compound YFe_2 has the cubic $MgCu_2$ C15 structure. There are eight YFe_2 formula units per simple cubic cell in this structure. The larger Y atoms occupy a cubic diamond lattice. Regular tetrahedra built of four smaller Fe atoms are centered at the fourfold-coordinated interstitial sites of the diamond structure. So the 26-atom cluster of $Fe_4Y_4Fe_{12}Y_6$, which consists of two distinct pairs of Fe and Y atoms, is chosen to represent the host compound YFe_2. While the cluster $Mn_4Y_4Fe_{12}Y_6$, with each Fe atom having one Mn atom in its nearest neighbor sites, is adopted to represent the pseudobinary compound $Y(Fe_{1-x}Mn_x)_2$ with low Mn concentration.

The DOS of the cluster $Mn_4Y_4Fe_{12}Y_6$, with a solid line, is depicted in Fig. 1. For comparison, we show the DOS of the host cluster $Fe_4Y_4Fe_{12}Y_6$ with a dashed line also in Fig. 1, which closely resembles the result obtained by the standard TBA method.[11] From these two curves, one can find that there is not a large change for the shape of the DOS when the Mn substitute at the Fe site of YFe_2, however, the positions of the peaks are changed. For majority-spin states, the main peaks below the Fermi level move to the direction of high energy, and meanwhile the peaks for minority-spin states move to low energy direction; thus the exchange splitting decreases with Mn diluting the Fe sublattice. As is well known, the origin of magnetism can be attributed to intraatomic and interatomic exchange interactions, and the Curie temperature is proportional to the exchange splitting, so the reduction of the exchange splitting gives rise to the decrease of the Curie temperature. Both the magnetization measurement and Mössbauer data show that the Curie temperature decreases almost linearly with the Mn content in the pseudobinary compound $Y(Fe_{1-x}Mn_x)_2$,[4,7] which is consistent with the above conclusion deduced from the electronic structure.

Table I lists the magnetic moments and electron occupation numbers of all atomic sites in the clusters $Fe_4Y_4Fe_{12}Y_6$ and $Mn_4Y_4Fe_{12}Y_6$. For comparison, let us first examine the result of the host cluster $Fe_4Y_4Fe_{12}Y_6$. It is noted that the

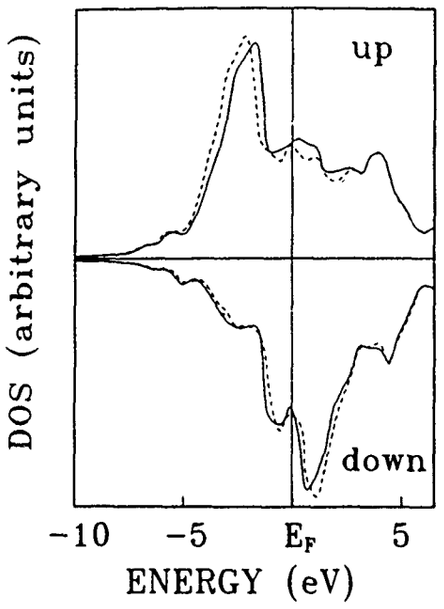

FIG. 1. Total density of states for the clusters $Mn_4Y_4Fe_{12}Y_6$ with a solid line and $Fe_4Y_4Fe_{12}Y_6$ with a dashed line. The spin-up and spin-down bands are normalized to the same scale for each cluster.

magnetic moments of Fe atoms are large and coupled ferromagnetically with small negative moments for Y atoms, which is consistent with the conclusion of the band calculation.[12]

By analyzing the result of the cluster $Fe_4Y_4Fe_{12}Y_6$ in Table I, one can see that the moments for both Fe and Y atoms tend to increase outwardly from inner sites due to the surface effect, which results from that the truncation of the cluster does not allow sufficient delocalization of the wave function in the solid to take place on the cluster surface. The surface effect is unavoidable for the present cluster calculation method, however, the atoms toward the central sites for a large cluster can reproduce the properties of the bulk solid.[13] In the present case, the calculated magnetic moment for the inner Fe atoms is $1.65\mu_B$, which is in fairly good agreement with the value of the band calculation,[12] while the moment of the inner Y atoms is $-0.58\mu_B$, a bit larger than the band calculated result, $-0.45\mu_B$, this difference is also attributed to the surface effect. It has been confirmed by many calculations that the cluster model tends to the same limit as band-structure methods when the cluster size increases, however, computation is too expensive for the larger cluster. For most physical properties, it has been observed that the three- to four-atom-shell cluster is sufficient.[14–16] For the magnetic moment, one can focus on trends instead of the absolute value.

TABLE I Electron occupation numbers and local magnetic moments in the different atomic sites of the clusters $Fe_4Y_4Fe_{12}Y_6$ and $Mn_4Y_4Fe_{12}Y_6$

	$Fe_4Y_4Fe_{12}Y_6$		$Mn_4Y_4Fe_{12}Y_6$

The atoms of Y in the compound YFe_2 were assumed to be nonmagnetic before the spin-polarized calculations of its band structures. The cluster and band theory calculations on YFe_2 both show that the Y atoms are spin polarized with a small negative moment, which can be attributed to the hybridization between Fe 3*d* and Y 4*d* states. According to the band-structure calculations, the main part of the 4*d* bands for Y are just above the Fermi level,[17] while most of the states just above the Fermi level for Fe are the 3*d* minority-spin states. So the 4*d* states of Y mainly hybridize with the minority-spin 3*d* states of its neighbor Fe, which results in the minority-spin dominating for the occupied 4*d* bands of Y, and hence a negative moment develops on the Y atoms.

Now, we study the effect of Mn on the magnetic moment of the pseudobinary compound $Y(Fe_{1-x}Mn_x)_2$. From Table I, it is noted that the moments of Mn and Fe atoms both are positive for the cluster $Mn_4Y_4Fe_{12}Y_6$, which shows that Mn moments are coupled ferromagnetically with Fe moments in the pseudobinary compound $Y(Fe_{1-x}Mn_x)_2$ with a low concentration of Mn. Furthermore, one can see that the magnetic moment of Mn is $0.71\mu_B$ and the Fe moment, $3.09\mu_B$, much less than that of the corresponding Fe atom in the host cluster, $3.80\mu_B$. The calculated Mn magnetic moment is in excellent agreement with the measurement results by polarized neutron scattering and NMR studies for the pseudobinary compound with low Mn content,[4] while the Fe moment decreases rapidly with Mn substitution for Fe atoms, which is also in accord with the experimental results.[4] In addition, the Y magnetic moment also decreases. The Mn magnetic moment deduced by Nagai *et al.*[5,6] is opposite to our calculated result, which may result from their oversimplified assumptions that *Y* atoms in the pseudobinary compound have no magnetic moment and that the hyperfine field at ^{89}Y is strictly proportional to the magnetic moments of nearest neighbor atoms.

III. CONCLUSIONS

We have performed first-principles self-consistent-field calculations on several embedded clusters representing the Mn-containing cubic Laves phase pseudobinary compound of YFe_2. Our calculated results for the first time provide an insight into its complex magnetic properties. The following is a summary of our results.

(1) In the compound YFe_2, the magnetic moments of Fe atoms order ferromagnetically and cause small antiparallel moments at Y sites. Substitutions of Mn atoms on Fe sites reduce the exchange splitting of this compound, and hence weaken its ferromagnetism.

(2) When the Fe atom has one Mn atom in its nearest neighbor sites, its magnetic moment decreases rapidly, owing to the strong hybridizations between the minority-spin $3d$ bands of Fe and Mn, while the Mn moment is $0.71\mu_B$, parallel to the Fe moments, which is in fairly good agreement with the neutron-scattering data and NMR studies.

Effects of Al substitution in Nd_2Fe_{17} studied by first-principles calculations

Ming-Zhu Huang and W. Y. Ching
Department of Physics, University of Missouri-Kansas City, Kansas City, Missouri 64110

We have studied the effect of Al substitution in Nd_2Fe_{17} compound by means of first-principles calculations. We first obtain the site-decomposed potentials for Fe from self-consistent calculation on Y_2Fe_{17} and the atomiclike potentials in the crystalline environment for Al and Nd. Calculations are carried out for a single Al substituting one Fe at four different Fe sites ($6c$), ($9d$), ($18f$), and ($18h$), two Al substituting two Fe ($18h$), and four Al substituting three Fe ($18h$) and one Fe ($18f$). Our results show that the Al moment is oppositely polarized to Fe. The average moment per Fe atom actually increases for Al substituting Fe ($18h$) and Fe ($18f$) is about the same for Al substituting Fe ($6c$), and is drastically reduced when replacing Fe ($9d$). Experimentally, Al is shown to be excluded from the ($9d$) sites because of the small Wigner–Seitz volume. When two Fe atoms are replaced by two Al atoms, the total moment is only slightly less than when only one Fe atom is replaced, and the M_s per Fe site actually increases, in agreement with the Mössbauer data. These results are analyzed in terms of the local atomic geometry and the charge transfer effect from the neighboring Fe to Al.

Recently, there has been a renewed interest in studying the substitutional effects in the R_2Fe_{17} intermetallic compounds (R represents a rare-earth element). The R_2Fe_{17} compounds in the rhombohedral Th_2Zn_{17} structure have high magnetic moments and are easy to process. However, none of the binary compounds exhibit uniaxial anisotropy at room temperature. The Curie temperature T_C is usually low, severely limiting their use as permanent magnets. Researchers soon discovered that interstitial doping by nitrogen and carbon can raise T_C substantially[1–4] and significantly modify the magnetocrystalline anisotropy of the R_2Fe_{17} compounds.

In the search for better and cheaper permanent magnets, elemental substitutions have also been explored in addition to interstitial doping, since it may also lead to an increase in Fe-Fe separation. The effects of elemental substitutions on the magnetic properties of R_2Fe_{17} compounds had been studied in the past.[5–8] More recently, Weitzer, Hiebl, and Rogl studied the magnetic behavior of Al and Ga substitution in R_2Fe_{17} compounds.[9] Yelon *et al.* carried out the neutron diffraction and Mössbauer effect studies of several $Nd_2Fe_{17-x}Al_x$ samples with x ranging from 0. to 9.4.[10] Li *et al.* studied the structural and magnetic properties of the combined effect of Al substitution and N doping.[11] These experiments demonstrate that Al has a preference to occupy the Fe ($18h$) sites when x is small and is excluded from the Fe ($9d$) sites at all concentrations.[10] The saturation moment and the T_C have a strong dependence on the Al concentration. Clearly, it is of fundamental interest to carry out theoretical calculations on the electronic structure and magnetic properties of the substituted compounds, and to trace the quantum mechanical origin of the improved magnetic properties.

In this report, we present the results of calculations on the electronic structure, local magnetic moment, charge, and spin density distribution for $Nd_2Fe_{17-x}Al_x$ ($x=0,1,2,4$). To our knowledge, there is not yet any theoretical calculation on the substitutional compounds of R_2Fe_{17}. For $x=1$, replacement of Fe by Al at each of the four Fe sites is studied even though the probability of Al occupation at certain Fe sites is almost zero. For $x=2$, we replace two Fe ($18h$) in the unit cell and for $x=4$, we replace three Fe ($18h$) and one Fe ($18f$). These proposed substitutional configurations are based on the neutron scattering data[10] which suggest Fe ($18h$) to be the most likely site for Al substitution, followed by the Fe ($18f$) site, and the occupation of the ($18h$) site tends to saturate at about half of the fraction. The lattice constants used in the calculation are from different sources,[10,12,13] and are listed in Table I. For simplicity, the experimental value for x has been rounded to the nearest integer. The calculated results are then correlated to the available experimental data.

We briefly outline the procedures of our calculation. We use the first-principles orthogonalized linear combination of the atomic orbitals method in the local spin density approximation (LSDA).[14] The computational details of this method have been described sufficiently elsewhere.[15] Since Nd contains localized $4f$ electrons for which the LSDA may not be a suitable theory, we start our calculation with Y_2Fe_{17} and $Y_2Fe_{17-x}Al_x$ but with the same lattice constants as for the corresponding $Nd_2Fe_{17-x}Al_x$ systems. We next obtain the site-decomposed Fe and Al potentials from these self-consistent calculations. Together with an atomiclike potential for Nd that has been used in the $Nd_2Fe_{17}B$ calculation,[16] we perform a series of spin-polarized calculations on $Nd_2Fe_{17-x}Al_x$. Interactions of the Nd-$4f$ orbitals with the neighboring atoms are taken into account with three of the Nd-$4f$ electrons fixed in the spin-up configuration.[16] Secular equations are solved for both spin cases at 11 special k points in the irreducible portion of the Brillouin zone to obtain the energy eigenvalues and wave functions. Spin-orbit couplings are neglected. Local spin magnetic moments are obtained from the wave functions and the overlap integrals using the Mulliken scheme.[17] In principle, for solid solutions of the type $Nd_2Fe_{17-x}Al_x$, a supercell calculation with sufficient statistical average over various possible configurations will be most desirable. However, such calculations will need a prohibitively large amount of computational time. For that reason, we limit our calculations to the original rhombohe-

dral cell containing two Nd atoms and 17 Fe atoms with some of them substituted by Al as specified above. Lattice relaxation at the substituted sites is not considered, and all calculations are for a single configuration. Even with these limitations, we believe our results are meaningful for comparing the effect of substitution at different Fe sites and with different Al concentrations.

Table I lists the calculated magnetic moments at the two Nd and the 17 Fe (Al) sites for $Nd_2Fe_{17-x}Al_x$. For $x=0$, the moments on the Fe sites of the same symmetry type are the same. With Al substitution, the symmetry is lowered and the moments at all sites are different. To better understand these results, we put an asterisk on the moment number to indicate that this particular site is a nearest neighbor (NN) to a substituted Al atom. Oppositely polarized moments are listed as negative numbers. The main results of Table I can be summarized as follows. (1) The moments on the Nd and Al are oppositely polarized. (2) For a single Al substitution, the average Fe moments are 1.90, 1.89, 1.65, and 1.50 μ_B for Al at the (18h), (18f), (6c), and (9d) site, respectively. For $x=0$, the calculated average Fe moment is 1.86 μ_B. The average Fe moment becomes particularly low when the Fe(9d) is substituted by Al. Neutron diffraction data show the (9d) site is excluded from Al occupation. (3) For those sites which are NN to a substituted Al (with the exception of the Al at the 9d site), the moments tend to increase relatively, showing the influence of the Al on the neighboring Fe atoms. Effective charge calculation based on the Mulliken scheme[17] shows an average charge transfer of the order of 1.8 electrons from the Fe sites to the Al. (4) Although the total moment decreases as x increases, the average moment per Fe atom actually increases with x. Yelon *et al.*[10] found an increase in the occupation fraction at the (6c), (18f), and (18h) sites with an increase in x up to $x=9.4$. The fractional occupation for Fe (18h) saturates at $x=4$. On the other hand, the hyperfine field from the Mössbauer spectra reaches a maximum at $x=2$, and then decreases with increase in x.

The microscopic origin as to why the Fe moment is increased or decreased depending on the specific site of Al substitution is more difficult to pin down. It will require extensive analysis of local local geometry and interatomic distances in relation to the electronic structure. The extended

The contour lines are: 0.01, 0.02, 0.04, 0.06, 0.08, 0.10, 0.15, 0.20, 0.25, 0.30, 0 40, 0.50 for charge density, and plus or minus of 0.001, 0.002, 0.003, 0 004, 0.006, 0 008, 0.01, 0.015, 0.020, 0.030, 0.040, 0 050 for the spin density. Negative numbers are indicated by dashed contours.

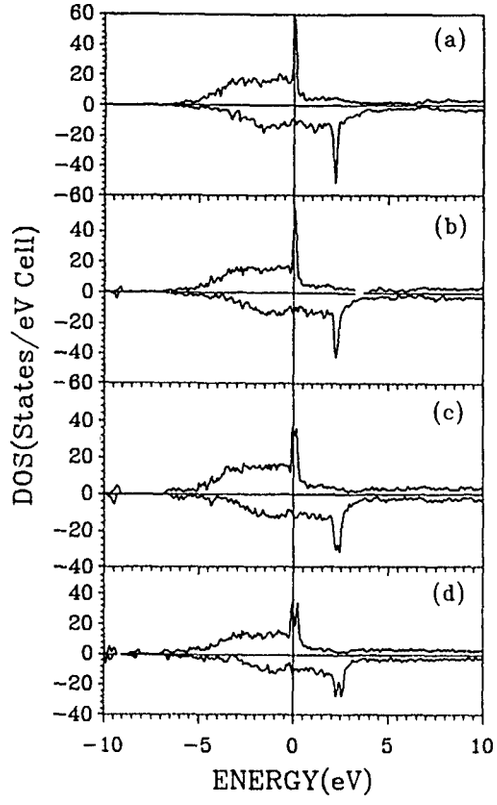

FIG. 2 Calculated total DOS for (a) Nd_2Fe_{17}; (b) $Nd_2Fe_{16}Al_1$; (c) $Nd_2Fe_{15}Al_2$, (d) $Nd_2Fe_{13}Al_4$. Positive values correspond to the majority spin band and negative values corresponds to the minority spin band.

nature of the Al-3s and Al-3p wave functions make it difficult to explain these rather complicated results based on simple arguments.

To further understand the calculated data in Table I and the role of Al atoms, we plot in Fig. 1, the charge and spin densities for Nd_2Fe_{17} and $Nd_2Fe_{16}Al_1$ with Al at the (18h) site. The plane of Fig. 1 is perpendicular to the c axis which contains the Fe (18h) atoms with the Fe (9d) atoms also very close to it and no Nd atoms. It is obvious that Al substitution breaks the local symmetry in the charge and spin distribution. The nonspherical and the negatively polarized spin density at the Al site are quite obvious. Similar distribution maps on other planes containing other Fe and Al sites are available but not shown. For Al substituting Fe (9d), charge- and spin-density maps reveal a much stronger interaction of Al with the nearby Fe atoms. This clearly indicates that the 9d site is small, hence unfavorable for Al occupation, in agreement with the conclusion of Ref. 10.

Figure 2 shows the total density of states (DOS) for $Nd_2Fe_{17-x}Al_x$ for $x=0$, 1, 2, and 4. The $x=1$ result is for Al substituting one Fe (18h). The Fermi energy is set at 0. The sharp peak near E_F for the majority spin band and at 2.5 eV for the minority spin band are from the Nd-4f states. The height of the Nd-4f peaks decreases as the Al concentration increases. The width of the occupied band is about 7 eV in all cases, but the total areas below E_F decrease because of reduced electron number as x increases. Partial DOS (not shown) indicates that Al-3p states are in the -4.5 to -4.7 eV range, and the split states near -9.5 eV originate from Al-3s. For $x=4$, Fig. 2(d) shows the splitting of the Nd-4f peaks and additional Al-3s states emerge at -8.5 eV. This simply reflects the fact that for $x=4$, Al replaces Fe atoms at two different sites, (18h) and (18f). The first-principles nature of the calculation accurately reflects the complicated interatomic interactions.

Magnetic and crystallographic order in α-manganese

A. C. Lawson, Allen C. Larson, M. C. Aronson,[a] S. Johnson,[b] Z. Fisk, P. C. Canfield,[c]
J. D. Thompson, and R. B. Von Dreele
Los Alamos National Laboratory, Los Alamos, New Mexico 87545

We have made time-of-flight neutron diffraction measurements on α-manganese metal. Powder diffraction measurements were made at 14 temperatures between 15 and 305 K, and single crystal measurements were made at 15 and 300 K. We found that the crystal structure of α-Mn is tetragonal below its Néel point of 100 K, with crystal symmetry $I\bar{4}2m$ and magnetic (Shubnikov) symmetry $P_I\bar{4}2_1c$. In agreement with the earlier results of Yamada *et al.*, there are six independent magnetic atoms, and we found that their moments are weakly temperature dependent. The onset of magnetic order causes slight changes in the atomic positions and in the average atomic elastic constant.

I. INTRODUCTION

α-manganese has a surprisingly complex cubic crystal structure with 58 atoms per body-centered cell.[1] The complexity is surprising, because most elements have simple structures. In the case of Mn, the complexity is thought to arise from an instability of the $3d$ electron shell that gives rise to the formation of "self-intermetallic" compounds. In other words, elemental Mn is actually an intermetallic compound between Mn atoms in different electronic configurations. This possibility was first pointed out by Bradley and Thewlis.[1]

α-Mn becomes antiferromagnetic at 95 K. Given the crystal structure, the magnetic structure is necessarily complex. The structure was solved by Yamada *et al.*,[2] who used single crystal neutron diffraction data and first principles magnetostructural analysis of heroic proportions.[2–4] We wished to examine the magnetic ordering in more detail by obtaining structural data at a large number of temperatures. The multitemperature requirement dictated the use of powder neutron diffraction. However, we found that information from single crystal data was essential to the complete solution of the problem.

II. EXPERIMENTAL METHOD

α-Mn was prepared by heating Johnson-Matthey grade I electrolytic Mn in a turbomolecular pumped system in the β-phase region until outgassing was complete and then cooling slowly through the α–β transition. The material was cooled from 900 °C to 755 °C over 5 h, from 755 °C to 655 °C over 200 h, and finally furnace cooled to room temperature. Powder was prepared by grinding the resulting material. Small single crystals were cut from an arc-melted ingot that was prepared from this material and annealed for a long time below the α–β transition. Neutron powder diffraction data were taken on an α-Mn sample at 14 temperatures between 15 and 305 K. We used the high intensity powder diffractometer (HIPD) and the Manuel Lujan, Jr. Neutron Scattering Center (LANSCE) at the Los Alamos National Laboratory.[5] We also obtained single crystal diffraction data at 15 and 300 K on the single crystal diffractometer (SCD) at LANSCE. Powder data were analyzed by Rietveld analysis using the general structure analysis system (GSAS).[6] This refinement package allows for the refinement of magnetic reflections arising from structures that can be described by Shubnikov groups. Powder data from six detector bands were corefined in the analysis. Allowance was made for 0.90% (vol) of MnO that was present in the powder and for some weak aluminum lines from the cryostat. Single crystal data were also refined using GSAS. In this case, magnetic multidomain effects were treated as a twinning problem.

III. RESULTS AND DISCUSSION

Since there was no evidence for an incommensurate structure, our approach to the analysis of our data was guided by the use of Shubnikov groups.[7,8] These are magnetic space groups that are supergroups of the ordinary crystallographic space groups, with certain symmetry elements replaced by "anti"-elements. The antielements are the ordinary translations, mirror planes, etc., familiar from crystallography, except that the spatial symmetry operator is augmented by a time-reversal operator that reverses the microscopic current

driving the magnetic moment of the atom to which it is applied. In this way, 1651 magnetic space groups can be obtained from the original 230 ordinary space groups. Only commensurate magnetic structures are described by the Shubnikov groups.

The space group of α-Mn is $I\bar{4}3m$. The neutron diffraction data indicate a body-anti-centered lattice, so that the Shubnikov group $P_I\bar{4}3m$, or one of its subgroups, is indicated. The cubic and rhombohedral subgroups did not work, and we found that the best fit was obtained with the tetragonal Shubnikov group $P_I\bar{4}2'm' \equiv P_I\bar{4}2c$, which is a subgroup of the tetragonal space group $I\bar{4}2m$. This is equivalent to the magnetic model of Yamada *et al.*[2] The meaning of the symbol $P_I\bar{4}2'm'$ is the same as the ordinary space group symbol $I\bar{4}2m$, except that (1) the ordinary body-centering operator is replaced by an operator that flips the spin (reverses the current) as the body centering is applied; (2) the mirror planes are replaced by operators that reverse the current as a magnetic atom is reflected; and (3) the twofold axes are replaced by operators that flip the spin (reverse the current) as the dyad operation is applied to a magnetic atom. (The distinction between spin flipping and reversing the current is important only for improper symmetry operators, such as mirror planes.)

y	"	"	"	"
z	"	"	0 035 43(4)	0.282 76(5)

In addition to the group $P_I\bar{4}2'm'$, we also tried fits with $P_I\bar{4}2m$, $P_I\bar{4}'2m'$, and $P_I\bar{4}\ 2'm$. (Of these four, only the first does not exclude a magnetic moment on site I by symmetry.) The models with $P_I\bar{4}2m$ and $P_I\bar{4}'2m'$ can be excluded by the single crystal data, which clearly show the presence of (300), (500), etc. magnetic reflections, in agreement with Yamada *et al.*[2] This is indicative of the presence of the two-fold antiaxis 2′. These reflections are not directly observable in the powder data because of overlapping allowed reflections, so that powder data cannot distinguish between 2 and 2′.

The quality of the powder fits for $P_I\bar{4}2'm'$ and $P_I\bar{4}'2m'$ is very similar, so that single crystal data was essential for making this distinction. However, the use of powder data is the only practical way of making observations at a large number of temperatures in a reasonable amount of time. The combination of both types of experiment was necessary in this case.

Since the magnetic structure of α-Mn is tetragonal, a tetragonal nuclear (or chemical) structure is implied. This structure was found by Rietveld refinement. The space group is $I\bar{4}2m$, and there are six unique atoms in the tetragonal unit cell. Above the Néel point, the structure is cubic with four unique atoms in the cell. There are 58 atoms per unit cell in each case.

Figure 1 shows the lattice constants of α-Mn plotted versus temperature. We emphasize that no tetragonal splitting of the diffraction lines was observed directly; rather, the metric tetragonality was found by testing the powder data with Rietveld refinement. Simultaneous refinements of the strain broadening were well behaved, and sensible atomic positions were found, so we have some confidence in this result. The average of the tetragonal lattice constants agree with previous diffraction measurements for which the low-temperature structure was taken to be cubic.[9,10]

The magnetic moments are plotted versus temperature in Fig. 2. These were obtained from the powder refinements using the form factors for the $3d^5 4s^2$ state of neutral Mn determined by Freeman and Watson.[11] Thus, we did not allow for a variation of the form factor among the atoms, as

did Yamada *et al.*[2] The moments we found are somewhat different from theirs, but the significant qualitative feature of groups of large and small moments is retained. The large moments on atoms I and II are somewhat temperature dependent, and the smaller moments on the remaining atoms are not.

The atomic positions also show the effects of magnetic ordering. Below the Néel temperature, the original four crystallographic sites of the cubic structure (Table I) split into the six sites of the tetragonal structure (Table II). The atomic positions obtained from the powder refinements are plotted versus temperature in Fig. 3. A diagram of the magnetic structure is given in the compilation by Wijn.[12] The Cartesian components of the magnetic moments at 15 K are given in Table II.

Magnetic ordering in α-Mn causes a stiffening of the lattice. Figure 4 shows the average mean-square thermal displacement, $\langle u^2 \rangle$, plotted versus temperature. The $\langle u^2 \rangle$ is obtained from the Debye–Waller factors from the Rietveld analysis of the powder data; it is averaged over atomic sites and direction.[13,14] We have made separate fits above and below the Néel temperature to the $\langle u^2 \rangle$ versus temperature data with a simple Debye model. The increase in Θ_{DW} observed at the Néel point (from 438 to 536 K) is quite large.

We report measurements of resistivity and transverse magnetoresistance ($B \perp I$) on a single crystalline sample of EuB_6 in magnetic fields to 18 T in a temperature range from 4 to 100 K. The ferromagnetic transition (T_c) determined by resistivity versus temperature at constant field varies from 10 to 25 K at zero and 4 T, respectively. The transition is completely suppressed at 8 T. A very large and negative tranverse magnetoresistance is observed in the entire temperature range investigated: -5% at 4 K and -20% at 100 K at 18 T. Finally, the effect of high applied magnetic field on the transport properties is investigated in the temperature range below T_c.

Micromagnetic calculations using a finite element technique rigorously describe the magnetic properties of novel, isotropic rare-earth-based composite magnets. Numerical results obtained for a composite material of $Nd_2Fe_{14}B$, $SmCo_5$ or $Sm_2(Fe_{0.8}Co_{0.2})_{17}N_{2.8}$ and α-Fe particles show that remanence, coercivity, and coercive squareness sensitively depend on microstructural features. Interparticle exchange interactions enhance the remanence by about 60% with respect to noninteracting particles for a mean-grain size approaching the exchange length of the soft magnetic phase and a significant percentage of α-Fe. On the other hand, exchange interactions between the phases suppress the nucleation of reversed domains and thus preserve a high coercive field. Therefore, optimally structured, isotropic composite magnets show remarkably high energy products exceeding 400 kJ/m^3.

I. INTRODUCTION

Composite materials of magnetically hard and soft particles are excellent candidates for high performance permanent magnets. In composite permanent magnets soft magnetic grains cause a high magnetization and hard magnetic grains induce a large coercivity provided that the particles are small and strongly exchange coupled. Owing to remanence enhancement, nanostructured, composite magnets are expected to improve the maximum energy product of permanent magnets dramatically.[1] Coehoorn, Mooij, and Waard[2] found a considerably increased remanence in melt-spun Nd-Fe-B magnets of nominal composition containing a substantial fraction of soft magnetic Fe_3B grains. Recently, Ding, McCormick, and Street[3] reported a maximum energy product of more than $(BH)_{max}=200$ kJ/m^3 in mechanically alloyed, isotropic Sm_7Fe_{93}-nitride powders where exchange interactions between a soft magnetic α-Fe and a hard magnetic $Sm_2Fe_{17}N_x$ phase cause a significant enhancement of the remanence. A similar behavior was found in composite magnets of $Nd_2Fe_{14}B$ and α-Fe produced by rapid solidification.[4,5] The maximum possible energy product is an intrinsic quantity $(BH)^*_{max}=J_s^2/(4\mu_0)$,[6] depending only on the spontaneous magnetic polarization J_s. In order to reach this theoretical maximum, it is required that the magnet maintains saturated until the opposing field reaches the value $-(1/2)(J_s/\mu_0)$.[7] In real magnets the remanent polarization J_r rather than the spontaneous magnetic polarization will determine the maximum energy product, $(BH)_{max}$. Within the framework of the Stoner–Wohlfarth theory,[8] which assumes noninteracting single domain particles, the remanent magnetic polarization is given by

$$J_r=J_s\langle\cos\vartheta\rangle, \tag{1}$$

where ϑ is the angle between the saturation direction and the easy axes and $\langle\ \rangle$ denotes an ensemble average. According to (1) J_r/J_s is 0.5 for an assembly of noninteracting and randomly oriented particles, whereas J_r/J_s is $2/\pi=0.637$ for microstructures with in-plane random texture.

A theoretical treatment of remanence enhancement must take into account interactions of the grains. Using a one-dimensional micromagnetic model, Kneller and Hawig[9] estimated the optimum microstructure of composite magnets to consist of hard grains embedded in a magnetically soft matrix with the lateral dimensions of both phases about equal to the domain wall width of the hard magnetic phase. Grönefeld[10] numerically calculated the remanence of composite magnets, solving Poisson's equation for the magnetization distribution on a lattice of magnetically hard and soft moments. The results show that almost all the magnetic moments of the soft magnetic phase become aligned parallel to the saturation direction, which corresponds to the average direction of the easy axes of the neighboring hard magnetic grains. Nieber *et al.*[11] and Skomski *et al.*[1] explicitly derived the magnetic properties of multilayers being composed of

 0021-8979/94/76(10)/7053/6/$6.00 © 1994 American Institute of Physics

magnetically soft and hard layers. This article gives a quantitative treatment of the correlation between the microstructure and the magnetic properties of isotropic, rare-earth based composite magnets. In order to describe magnetization processes of realistic microstructures, the classical Stoner–Wohlfarth theory[8] has been extended to nonellipsoidal and interacting particles using a finite element technique.

Section II of this article introduces the micromagnetic concepts and the computational methods of the simulation model. Section III describes the two- and three-dimensional grain structures used for the calculations. Section IV presents the basic magnetic properties of nanocrystalline, composite magnets. Section V compares the demagnetization curves obtained for composite materials of $Nd_2Fe_{14}B$, $SmCo_5$, $Sm_2(Fe_{0.8},Co_{0.2})_{17}N_{2.8}$ and α-Fe particles.

II. MICROMAGNETIC AND COMPUTATIONAL BACKGROUND

Minimizing the total magnetic Gibb's free energy with respect to the magnetic polarization $\mathbf{J}_s$, subject to the constraint that $|\mathbf{J}_s|$ is constant, yields a stable equilibrium state of a magnetic structure. If one neglects magnetoelastic and surface anisotropy effects, the magnetic Gibb's free energy ϕ_t of a ferromagnetic specimen in an applied magnetic field is the sum of the exchange energy, the magnetocrystalline anisotropy energy, the stray field energy, and the magnetostatic energy of the $\mathbf{J}_s$ in an external field $\mathbf{H}_{ext}$.[12] For uniaxial magnetic materials, where the direction of $\mathbf{J}_s$ may be described by the angle α between $\mathbf{J}_s$ and the easy axis, ϕ_t is given by[13]

$$\phi_t = \int \{A[(\nabla\vartheta)^2+(\nabla\varphi)^2 \sin^2\vartheta]+K_1 \sin^2\alpha + K_2 \sin^4\alpha - \tfrac{1}{2}\mathbf{J}_s\cdot\mathbf{H}_d-\mathbf{J}_s\cdot\mathbf{H}_{ext}\}d^3r, \quad (2)$$

where K_1, K_2 are the anisotropy constants, and A is the exchange constant. Using the polar angle φ and the azimuth angle ϑ to represent $\mathbf{J}_s$, automatically fulfills the nonlinear constraint, $|\mathbf{J}_s|=J_s$, during minimization. All energy terms but the stray field energy, $\phi_s=-\frac{1}{2}\int\mathbf{J}_s\cdot\mathbf{H}_d d^3r$, depend only locally on the magnetic polarization $\mathbf{J}_s$. The demagnetizing field $\mathbf{H}_d$ follows from magnetic volume charges, $\nabla\cdot\mathbf{J}_s$, within the grains and magnetic surface charges, $\mathbf{J}_s\cdot\mathbf{n}$ ($\mathbf{n}$ denotes the surface normal) at the grain boundaries. Owing to these long-range contributions of $\mathbf{J}_s$ to $\mathbf{H}_d$, the direct evaluation of the total magnetic Gibb's free energy requires both large memory and long computation time. Introducing a magnetic vector potential to treat the demagnetizing field eliminates long-range interactions from the total Gibb's free energy.[14,15] Brown[16] showed that the stray field energy ϕ_s due to $\mathbf{J}_s(\mathbf{r})$ can be approximated by an upper bound, given by

$$\phi_s \leq W[\mathbf{J}_s,\mathbf{A}]=\frac{1}{2\mu_0}\int(\nabla\times\mathbf{A}-\mathbf{J}_s)^2 d^3r, \quad (3)$$

where $\mathbf{A}$ is an arbitrary continuous vector whose derivatives are also continuous everywhere. The functional W if minimized with respect to $\mathbf{A}$, makes $\mathbf{A}$ equal to the magnetic vector potential $\nabla\times\mathbf{A}=\mu_0\mathbf{H}_d+\mathbf{J}_s$. W itself reduces to the stray-field energy ϕ_s. Replacing the stray-field energy in Eq. (2) by $W[\mathbf{J}_s,\mathbf{A}]$ leads to an auxiliary functional whose local minima are in one-to-one correspondence to those of the total Gibb's free energy.[14] Fredkin and Koehler[17] originally applied a magnetic vector potential in micromagnetic finite element calculations, in order to investigate magnetization processes in irregular shaped particles.

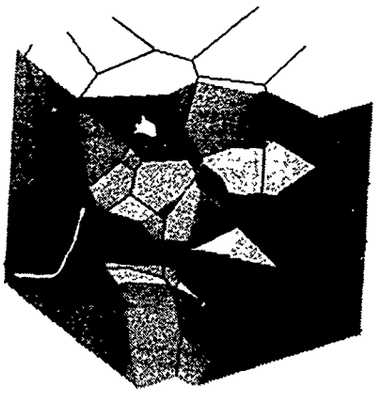

FIG. 1. Grains at the surface and in the interior of the cubic model magnet consisting of 64 irregularly shaped grains.

The linear interpolation of the magnetization angles and of the magnetic vector potential on triangular or tetrahedral elements gives an algebraic optimization problem. Since the magnetic polarization $\mathbf{J}_s$ and the magnetic vector potential $\mathbf{A}$ are two independent variables, the minimization can be performed simultaneously with respect to $\mathbf{J}_s$ and $\mathbf{A}$. Thus convergence difficulties of iterative techniques, which alternate between solving for a magnetic scalar potential for fixed magnetization and minimizing the total energy for fixed demagnetizing field, can be avoided. Among standard numerical minimization techniques, a preconditioned quasi-Newton conjugate gradient method[18] proved to be most efficient for minimizing the total Gibb's free energy of magnetic microstructures. The functional $W[\mathbf{J}_s,\mathbf{A}]$ is an integral not only over the magnetic particle but over the whole space. In principle, the finite element mesh has to be extended over a large region outside the particle. Applying spatial transformations to evaluate the integral reduces the size of the external mesh and provides an accurate approximation of the stray-field energy.[19,20]

III. MAGNETIC MICROSTRUCTURES

Modeling of grain growth yields realistic two- or three-dimensional microstructures. Starting from randomly located seed points, grains grow with constant growth velocity in each direction.[21]

Figure 1 shows a cut through a cubic model magnet consisting of 64 irregularly shaped particles. Figure 2 gives the distribution of the grain diameters. In order to describe composite magnets, material parameters of magnetically hard and soft phases are assigned to each grain. Beginning with the smallest grains, a fraction of the particles are considered to be magnetically soft. Thus the mean grain size of

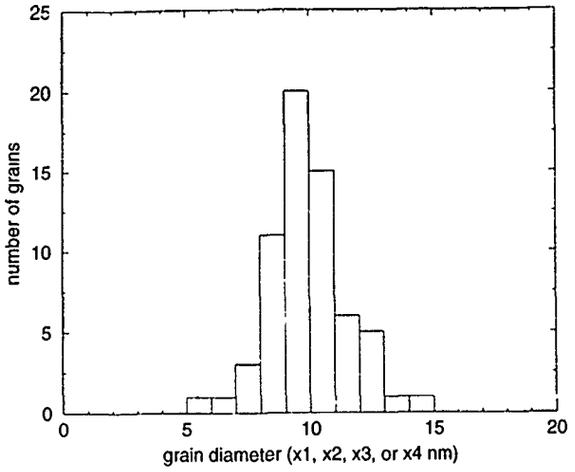

FIG. 2. Grain size distribution of the three-dimensional microstructure. The grain diameter is defined by the diameter of a sphere with equal volume.

the soft magnetic particles becomes smaller than that of the hard magnetic grains which has been been found in rapidly solidified, Nd-Fe-B based composite magnets.[5] The randomly oriented particles have direct contact and are coupled by short-range exchange and long-range magnetostatic interactions.

The basic magnetic properties of isotropic, composite magnets have been calculated for three-dimensional microstructures. However, the computational effort is much smaller in two-dimensional calculations where the magnetization is constrained in a plane and taken to be uniform in a direction perpendicular to this plane. The two-dimensional approximation of naturally three-dimensional magnetization processes does not severely influence the magnetic properties.[20] Thus, the comparison of the magnetic properties of various rare-earth-based composite magnets has been performed using two-dimensional microstructures. The two-dimensional grain structure consists of 30 grains with nearly hexagonal shape. Table I gives the intrinsic magnetic properties of the different materials used for the calculations.

IV. BASIC MAGNETIC PROPERTIES OF ISOTROPIC, COMPOSITE MAGNETS

Figure 3 shows the demagnetization curves of a $Nd_2Fe_{14}B$ and α-Fe magnet for increasing percentage of soft magnetic phases. The solid and the dashed line corresponds to the demagnetization curves for a mean grain size of 10 and 20 nm, respectively. For the calculations, the material parameters of $Nd_2Fe_{14}B$ and α-Fe at room temperature have been used. The numerical results clearly show that the magnetic properties of nanocrystalline, composite magnets drastically changes with the amount of α-Fe and with the average grain size.

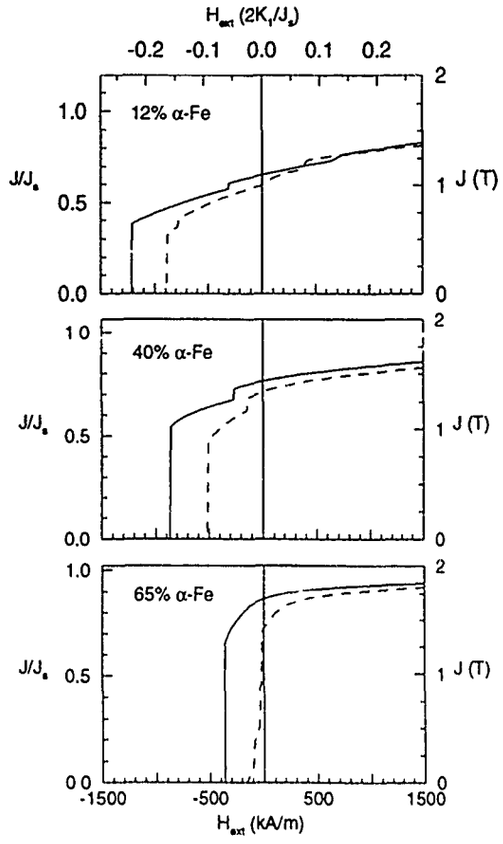

FIG. 3. Demagnetization curves of isotropic, $Nd_2Fe_{14}B$-based, composite magnets containing 12%, 40%, and 65% α-Fe. The different curves refer to 10 nm (solid line) and 20 nm (dashed line) mean grain size.

Figure 4 gives the remanence, the coercive field, and the maximum energy product of $Nd_2Fe_{14}B$-based composite magnets as a function of the amount of α-Fe for a mean grain size of 10 and 20 nm. The remarkably high remanence of nanocrystalline composite magnets has to be attributed to (1) the increased spontaneous magnetization of the soft magnetic phase and (2) remanence enhancement owing to interparticle exchange interactions. Figure 4 compares both con-

TABLE I. Intrinsic magnetic properties at $T=300$ K of hard and soft magnetic materials used for the calculations J_s, K_1, K_2, A, and T_c denotes the spontaneous magnetization, the first and second anisotropy constants, the exchange constant, and the Curie temperature, respectively.

	J_s (T)	K_1 (J/m^3)	K_2 (J/m^3)	A (J/m)	T_c (K)	Ref.

α-Fe	2.15	4.6×10^4	1.5×10^4	25.0×10^{-12}	1043	30

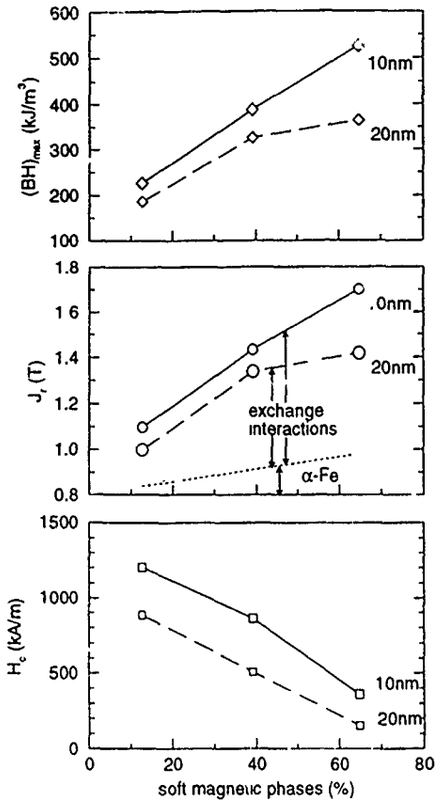

FIG. 4. Maximum energy product, remanence, and coercive field in isotropic, $Nd_2Fe_{14}B$-based, composite magnets as a function of the volume fraction of α-Fe. The different curves refer to 10 nm (solid line) and 20 nm (dashed line) mean grain size. The dotted line gives the remanence of the samples according to the Stoner–Wohlfarth theory.

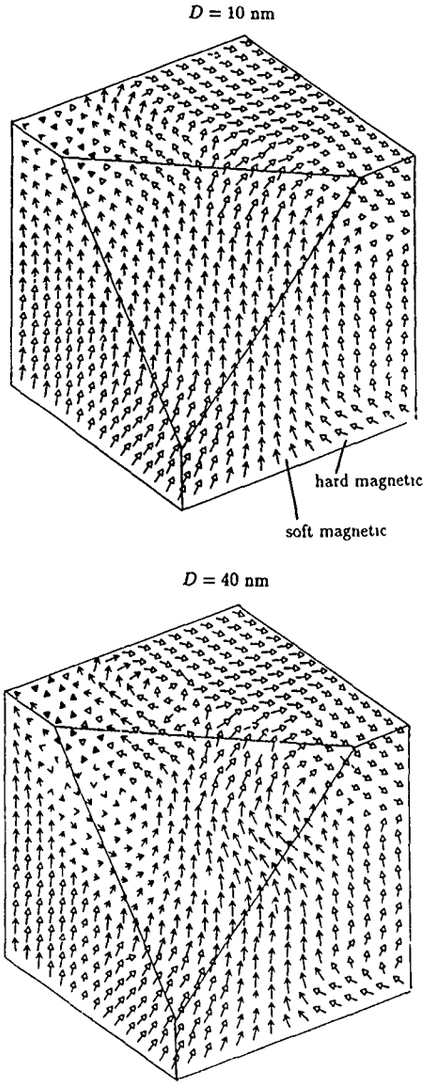

FIG. 5. Spin arrangements for zero applied field at the surface and in the interior of a composite magnet of 60% $Nd_2Fe_{14}B$ and 40% α-Fe for 10 and 40 nm mean grain size. The arrows with the closed heads denote the magnetic moments within hard magnetic grains, the arrows with the open heads denote the magnetic moments within soft magnetic grains.

tributions to the remanence. According to the Stoner–Wohlfarth theory,[8] an isotropic $Nd_2Fe_{14}B$ magnet has a remanence of $J_r = J_s/2 \approx 0.8$ T. The dotted line gives the remanence of the composite material assuming noninteracting particles. The remanence increases linearly with the percentage of α-Fe. The difference between the numerical results and the Stoner–Wohlfarth theory has to be entirely attributed to intergrain exchange interactions. In nanocrystalline materials exchange interactions align the magnetic moments parallel to the saturation direction and thus considerably increase the remanence. In soft magnetic particles exchange interactions override competitive micromagnetic effects to a greater extent than in hard magnetic grains. Therefore, remanence enhancement due to interparticle interactions increases with increasing amount of α-Fe.

The spin arrangements for zero applied field, given in Fig. 5 for a composite magnet of 60% $Nd_2Fe_{14}B$ and 40% α-Fe, demonstrate the effect of the particle size. For a mean grain size of 10 nm the exchange length of α-Fe, $l_{ex} = \pi\sqrt{A/(J_s^2/\mu_0)}$, approaches the particle diameter. Thus, almost all the magnetic moments of the soft magnetic phase are aligned parallel to the saturation direction. The ratio of the remanent to saturation polarization shows a remarkably high value of $J_r/J_s = 0.79$. For a mean grain size of 40 nm, stray field effects determine the direction of $\mathbf{J}_s$ within the soft magnetic phase. Exchange interactions influence the magnetization of the soft magnetic particles only near the interface between hard and soft magnetic phases. The ratio of the remanent to saturation polarization reaches only $J_r/I_s = 0.66$.

The coercive field decreases with increasing amount of α-Fe. Nevertheless, exchange interactions between the hard and soft magnetic phases preserve a high coercive field. As a consequence the maximum energy product resembles the behavior of the remanence. For a mean grain size of 10 nm and more than 50% α-Fe content, isotropic $Nd_2Fe_{14}B$-based composite magnets show maximum energy products exceeding 400 kJ/m^3. The self-demagnetizing field deteriorates the coercive squareness owing to reversible rotations or magnetization reversal within large soft magnetic regions. Thus, the increase of $(BH)_{max}$ with the increasing percentage of α-Fe is less significant for a grain size of 20 nm.

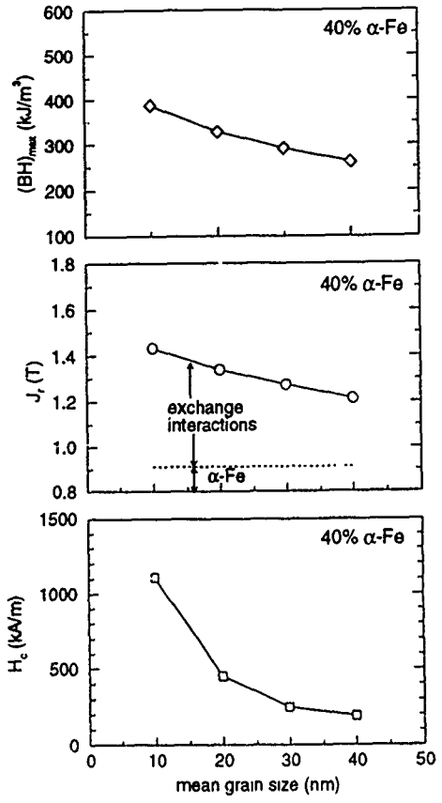

FIG. 6. Maximum energy product, remanence, and coercive field as a function of the mean grain size for a composite magnet consisting of 60% $Nd_2Fe_{14}B$ and 40% α-Fe. The dotted line gives the remanence of the samples according to the Stoner–Wohlfarth theory.

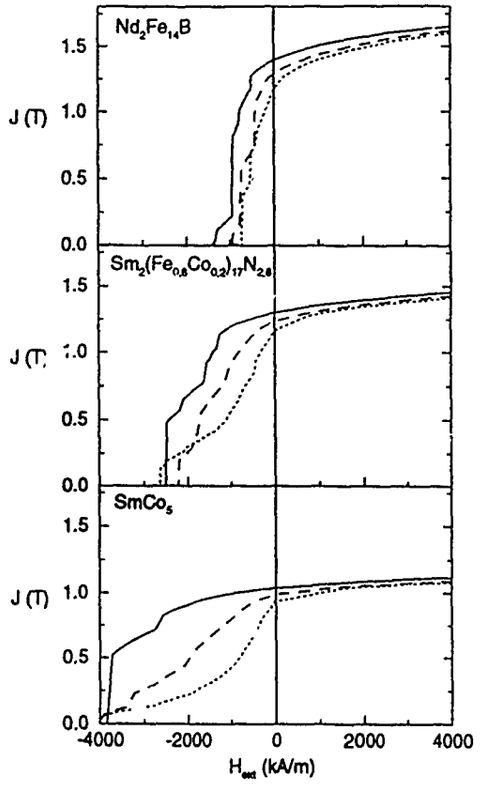

FIG. 7. Demagnetization curves of isotropic, rare-earth-based composite magnets containing 80% $Nd_2Fe_{14}B$, $Sm_2(Fe_{0.8}Co_{0.2})_{17}N_{2.8}$, or $SmCo_5$, and 20% α-Fe for an average grain diameter of 10 nm (solid line), 20 nm (dashed line), and 40 nm (dotted line).

Figure 6 shows the remanence, the coercive field, and the maximum energy product as a function of the mean grain size for a composite magnet of 60% $Nd_2Fe_{14}B$ and 40% α-Fe. Remanence and coercivity decrease with increasing grain size. In nanocrystalline, composite magnets two competitive effects determine the size dependence of coercivity: (1) Magnetic inhomogeneities owing to short-range exchange interactions between hard magnetic grains favor the nucleation of reversed domains. The nucleation field of hard magnetic grains coupled by short-range exchange interactions decreases with decreasing grain size.[22] (2) Exchange interactions between the different phases, suppress the nucleation of reversed domains within the soft magnetic particles. The nucleation field of a soft magnetic grain embedded within a hard magnetic phase decreases with increasing grains size.[23–26] The nucleation of reversed domains within the soft magnetic particles may cause magnetization reversal in neighboring hard magnetic grains, depending on the distribution of magnetically hard and soft phases, on the shape of the grains, and on the orientation of the easy axes. If the reversal of the soft magnetic particles initiates a cascade-type demagnetization process, the coercive field will be determined by the nucleation field of the soft magnetic particles and thus will decrease with increasing grain size.

V. COMPARISON OF ISOTROPIC RARE-EARTH-BASED COMPOSITE MAGNETS

Owing to a remarkably high magnetocrystalline anisotropy, novel nitrided intermetallic compounds have a large potential for composite permanent magnets. The demagnetization curves of Fig. 7 characterize the magnetic properties of novel, isotropic rare-earth-based composite magnets. Figure 7 compares the demagnetization curves for an average grain diameter of 10, 20, and 40 nm, obtained for composite magnets of 80% $Nd_2Fe_{14}B$, $Sm_2(Fe_{0.8}Co_{0.2})_{17}N_{2.8}$, or $SmCo_5$, and 20% α-Fe. The results clearly show that the coercive squareness decreases with increasing grain size for all materials. The demagnetization curves show a dip at the nucleation field of the soft magnetic phase. The comparison of the demagnetization curves for a mean grain size of 10 nm clearly shows that the nucleation field of the soft magnetic phase increases with increasing magnetocrystalline anisotropy of the hard magnetic phase. Exchange hardening becomes less effective with increasing grain size. Consequently, for a mean grain size of 40 nm, the nucleation field of the soft magnetic phase approaches nearly the same value for all composite materials. Nevertheless, the coercive field and the shape of the demagnetization curves differ drastically for the different materials. In $Nd_2Fe_{14}B$-based magnets the nucleation of reversed domains within the soft magnetic phase initiates a cascade-type demagnetization of neighbor-

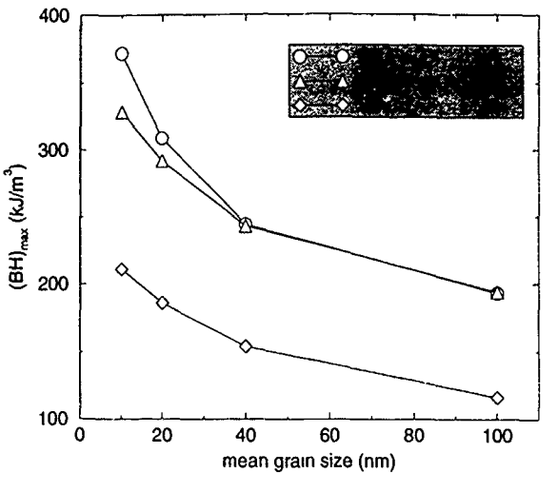

FIG. 8. Maximum energy product rare-earth-based composite magnets containing 20% α-Fe as a function of the mean grain size.

ing hard magnetic particles at a slightly increased external field. In composite magnets based on nitrided intermetallic compounds or $SmCo_5$, the elevated magnetocrystalline anisotropy of the hard magnetic phase preserves a high coercive field despite the reversal of the soft magnetic particles. However, the nucleation of reversed domains within the soft magnetic phase deteriorates the shape of the demagnetization curves.

Figure 8 compares the maximum energy product as a function of the grain size for composite magnets of 80% hard magnetic phase and 20% α-Fe. All materials but $SmCo_5$ show an energy product of about 300 kJ/m^3 for a mean grain size $D=20$ nm. Because of a high coercive field, $Sm_2(Fe_{0.8}Co_{0.2})_{17}N_{2.8}$-based composite magnets will show a better temperature stability and thus are superior to $Nd_2Fe_{14}B$-based magnets.

VI. CONCLUSIONS

Numerical micromagnetic calculations reveal the microstructural and micromagnetic conditions required for high remanent and high coercive composite magnets. The excellent hard magnetic properties of optimally structured composite magnets have to be attributed to intergrain exchange interactions. (1) Exchange interactions enhance the remanence by more than 40% as compared to the remanence of noninteracting particles. (2) Exchange hardening of the soft magnetic particles preserves a sufficiently high coercive field. The numerical studies show that remanence enhancement and exchange hardening are most effective for an average grain size comparable with the exchange length of the soft magnetic phase and a significantly high amount of soft magnetic particles.

Aligned two-phase magnets: Permanent magnetism of the future? (invited)

R. Skomski
Department of Pure and Applied Physics, Trinity College, Dublin 2, Ireland

Micromagnetic calculations are used to investigate coercivity and energy products of magnets consisting of an aligned hard-magnetic skeleton phase and a soft-magnetic phase with high saturation magnetization. Compared to the present-day theoretical limit of 516 kJ/m^3 for single-phase $Nd_2Fe_{14}B$, the energy product in suitable nanostructured $Sm_2Fe_{17}N_3/Fe_{65}Co_{35}$ composites is predicted to be as high as 1090 kJ/m^3. The influence of the skeleton's texture and shape is discussed, and aligned nanocrystalline two-phase magnets are compared with remanence-enhanced isotropic magnets. In particular it is shown how the nucleation-based analytical approach breaks down in the isotropic limit. Finally, we outline conceivable processing methods and discuss potential applications of "megajoule" magnets.

I. INTRODUCTION

A key figure of merit of permanent magnetic materials is the energy product $(BH)_{max}$, which describes the ability to store magnetostatic energy. Energy product increases with coercivity H_c and remanence M_r but can never exceed the value $\mu_0 M_r^2/4$ corresponding to an ideal rectangular hysteresis loop. Since $M_r \leq M_0$, the spontaneous magnetization M_0 yields an "intrinsic" limit $(BH)_{max} \leq \mu_0 M_0^2/4$, but if magnetization were the only consideration then α iron with $\mu_0 M_0 = 2.15$ T would be used for permanent magnets with energy products as high as 920 kJ/m^3. In fact, the coercivity of bcc iron is so low that energy products of iron magnets are only of order 1 kJ/m^3, and in the past it was necessary to resort to cumbersome bar and horseshoe shapes to avoid spontaneous demagnetization into a multidomain state by the magnet's own magnetostatic field. For this reason the quest for improved energy product has involved a search for compounds with a large magnetization combined with the strong uniaxial anisotropy needed to develop hysteresis.

In former years, the problem was to achieve the necessary anisotropy, but more recently the focus has shifted to the problem of enhancing the magnetization. Modern high-performance magnets such as $SmCo_5$, $Nd_2Fe_{14}B$, or the interstitial nitride $Sm_2Fe_{17}N_3$ consist of $3d$ atoms which are exchange coupled to rare-earth atoms which provide the uniaxial anisotropy required of a permanent magnet.[1–7] In reality, coercivity as high as 4.4 T has been achieved in $Sm_3Fe_{17}N_3$-based magnets,[8] but for practical purposes there is usually no call for coercivity very much greater than $M_0/2$. On the other hand, the magnetization is reduced due to the rare-earth and nonmagnetic elements. The light rare-earths' atomic moments are at best slightly larger than that of iron, but they occupy more than three times the volume. Nevertheless, it has been possible to use $Nd_2Fe_{14}B$ which has $\mu_0 M_0 = 1.61$ T and $\mu_0 M_0^2/4 = 516$ kJ/m^3 to achieve room-temperature energy products exceeding 400 kJ/m^3 in laboratory-scale magnets.[2] At about 200 °C, which is a technologically important temperature region, $Sm_2Fe_{17}N_3$ is potentially the best permanent magnetic material,[1,5] but here suitable processing methods have not yet been developed.

Energy product has doubled every twelve years since the beginning of the century, and much effort is being made to yield further quantitative and qualitative progress in the performance of permanent magnetic materials.[9] However, the outlook for discovering new ternary phases with magnetization significantly higher than that of those available, at present, is poor.[3] Permanent magnets based on the appearance of a new rare-earth iron intermetallic phase could offer better temperature stability, yet higher anisotropy field or improved corrosion resistance, but the scope for significant improvements in the spontaneous magnetization is very limited. For instance, interstitial modification with small atoms such as nitrogen or carbon is effective for enhancing Curie temperature and anisotropy,[1,5,10,11] but it has rather little effect on the magnetization—the moment increase is, on the whole, a zero sum game.[3]

In the case of isotropic magnets, which are often more easy to produce than oriented magnets, the comparatively low remanence $M_r \approx M_0/2$ reduces the theoretical energy product by a factor 4. However, the production of nanocrystalline composites such as $Nd_2Fe_{14}B/Fe_3BFe$ and $Sm_2Fe_{17}N_3/Fe$ by melt spinning[12] and mechanical alloying,[13] respectively, shows that it is possible to combine the high magnetization of soft-magnetic materials and the surplus anisotropy of rare-earth intermetallics. Soft magnetic phases such as bcc iron often reduce the energy product by degrading coercivity, but if the soft regions are small enough then exchange coupling stabilizes the magnetization direction of the soft phase. This kind of exchange coupling improves the low remanence of the isotropic hard phase,[12–16] but the energy product, though improved with respect to the isotropic single-phase rare-earth material, does not reach the level attained in oriented single-phase rare-earth magnets. In other words, new approaches are necessary if the energy product is ever to double again.

Recent work by Skomski and Coey[3,17,18] has shown how it should be possible to substantially increase the energy product in *oriented* nanostructured two-phase magnets by exploiting exchange coupling between hard and soft regions (Fig. 1). The idea behind these systems is to break out of the straightjacket of natural crystal structures by artificially structuring new materials. The concept is similar to that of the $4f$-$3d$ intermetallics themselves, but on a different scale, where the atoms are replaced by a mesoscopically structured hard-magnetic skeleton with surplus anisotropy and small soft-magnetic blocks. Based on analytical calculations, a

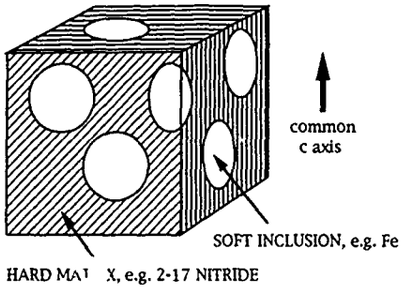

FIG. 1. Spherical soft inclusions in an aligned hard matrix.

well-defined and *realistic* upper limit to the energy product of permanent magnets has been established, and energy products of order 1 MJ/m^3 have been predicted for suitable multilayered and random structures.

Here, we summarize the background and results of these calculations, relate them to the problem of remanence enhancement in isotropic magnets, and draw conclusions with respect to future developments in permanent magnetism.

II. BACKGROUND

A. Micromagnetic free energy

To predict the performance of a permanent magnetic material we have to calculate the average magnetization $\langle \mathbf{M} \rangle$ as a function of the applied magnetic field $\mathbf{H}=H\mathbf{e}_z$. A convenient starting point is the (magnetic) free energy F, where the properties of the magnetic material enter as temperature-dependent parameters. Locally stable magnetic configurations are obtained by putting $\delta F/\delta \mathbf{M}(\mathbf{r})=0$, where $\delta .../\delta \mathbf{M}(\mathbf{r})$ denotes the functional derivative with respect to the magnetization $M(\mathbf{r})=M_0(\mathbf{r})\mathbf{s}(\mathbf{r})$ with $s^2=1$. Typically, the free energy of permanent magnets exhibits two or more metastable equilibrium states, and tracing the magnetic configuration $\mathbf{s}(\mathbf{r})$ as a function of an external field $\mathbf{H}=H\mathbf{e}_z$ is quite a demanding task.

On a mesoscopic level, i.e., assuming that the magnetization is a continuous variable, the free energy of a permanent magnet reads[19,20]

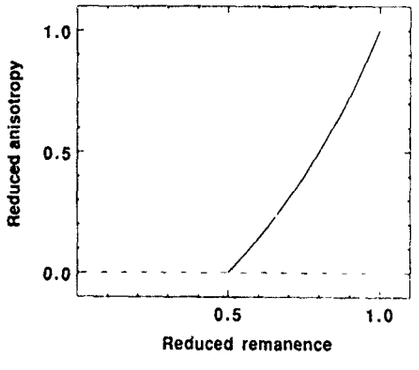

FIG. 2. Dependence of the reduced effective anisotropy constant $K_{\rm eff}/K_h$ on the reduced remanence M'/M_h. $M'/M_h=1/2$ and $M_r/M_h=1$ mean isotropic texture and complete alignment, respectively.

$$F=\int [\eta_{xc}(\mathbf{r})+\eta_a(\mathbf{r})+\eta_H(\mathbf{r})+\eta_{ms}(\mathbf{r})]d\mathbf{r}. \tag{1}$$

The contributions to the free-energy density are (i) the exchange free-energy density $\eta_{xc}=A(\mathbf{r})[\nabla \mathbf{s}(\mathbf{r})]^2$, where the exchange stiffness $A(\mathbf{r})$ describes the tendency towards parallel spin alignment, (ii) the energy density of the (uniaxial) anisotropy

$$\eta_a=-(K_1+2K_2+3K_3)(\mathbf{ns})^2+(K_2+3K_3)(\mathbf{ns})^4 -K_3(\mathbf{ns})^6, \tag{2}$$

where $\mathbf{n}$ is the unit vector of the local c-axis direction, (iii) the Zeeman energy density $\eta_H=-\mu_0 M_0(\mathbf{r})Hs_z(\mathbf{r})$, where $\mathbf{H}=H\mathbf{e}_z$ is the external magnetic field, and (iv) the magnetostatic dipole interaction

$$\int \eta_{ms}(\mathbf{r})d\mathbf{r}=-\frac{1}{2}\sum_{i,j=1}^{3}\int \mathrm{K}_{ij}(\mathbf{r}-\mathbf{r}') \times M_i(\mathbf{r})M_j(\mathbf{r}')d\mathbf{r}d\mathbf{r}', \tag{3}$$

with $\mathrm{K}_{ij}(\mathbf{r})=\mu_0(3r_ir_j-\delta_{ij}r^2)/(4\pi r^5)$ and $\mathbf{M}(\mathbf{r})=\Sigma_i M_i(\mathbf{r})\mathbf{e}_i$. Note that putting $\mathbf{n}(\mathbf{r})=\mathbf{e}_z$ in Eq. (2) is equivalent to the familiar expression $\eta_a=K_1\sin^2\theta+K_2\sin^4\theta+K_3\sin^6\theta$, where θ is the angle between magnetization and z direction.

B. Coercivity and energy product

Mechanical work to be done by a permanent magnet implies a magnetic hardness (coercivity) which keeps the magnetization in the desired direction. If the coercivity H_c is too small, or if the hysteresis loop has an unfavorable shape, then the energy product won't reach the theoretical value $\mu_0 M_0^2/4$ deduced from the saturation magnetization M_0.

Depending on the real structure of a permanent magnet, there are different hardening mechanisms. Here we treat aligned nanostructured two-phase magnets as nucleation-controlled magnets. The nucleation field $H_N=-H$ is defined as the (reverse) field at which the original state $\mathbf{s}(\mathbf{r})\approx\mathbf{e}_z$ becomes unstable. Mathematically, this requires the determinant of the continuous matrix $\delta^2F/\delta\mathbf{s}(\mathbf{r})\delta\mathbf{s}(\mathbf{r}')$ to vanish. Note, however, that the introduction of pinning centers is a potential way of improving the coercivity by inhibiting the propagation of the reversed nucleus, so $H_N\leq H_c$ is a lower limit to the coercivity.

The determination of H_N is a fairly demanding task,[19–21] and we have to introduce suitable approximations. Due to the long-range character of $\mathrm{K}_{ij}(\mathbf{r})$, the magnetostatic interaction is the most complicated one. A simple, though nontrivial, approximation is to replace the external magnetic field by $H_{\rm eff}=H-D\langle M_z\rangle$, where D is the demagnetizing factor. It has been shown quite generally[20–22] that for a homogeneous ellipsoid

$$H_c\geq\frac{2K_1}{\mu_0 M_0}-DM_0, \tag{4}$$

where the factor $D\,M_0$ arises from the gain in magnetostatic energy due to an incoherent rotation process. The $>$ sign in Eq. (4) indicates that incoherent rotation costs exchange en-

ergy, but the corresponding coercivity contribution scales as $A/(\mu_0 M_0 L^2)$, where L is the magnet's size, and is practically negligible. In the case of coherent rotation (the Stoner–Wohlfarth model), $H_N=2K_1/\mu_0 M_0-(1-3D)M_0/2$, and there is no influence of a "demagnetizing" field in spherical magnets where $D=1/3$. The result of the Stoner–Wohlfarth model is consistent with Eq. (4).

Equation (4) is called Brown's paradox, because real permanent magnets always seem to violate this inequality. This violation is due to the existence of inhomogenities in real magnets while Eq. (4) applies to homogeneous ellipsoids only.[21,22] In the following, we restrict ourselves to the so-called "intrinsic" $D=0$ hysteresis loop of macroscopic magnets, from which the energy product is determined.[23]

III. MODEL AND CALCULATION

To determine the nucleation field we assume ideal alignment of the hard phase, i.e., $\mathbf{n}(\mathbf{r})=\mathbf{e}_z$, and rewrite $\mathbf{s}(\mathbf{r})\approx\mathbf{e}_z$ as

$$\mathbf{s}=\sqrt{1-m^2}\mathbf{e}_z+\mathbf{m}, \quad \mathbf{m}=s_x\mathbf{e}_x+s_y\mathbf{e}_y, \quad m^2\ll 1. \tag{5}$$

Now series expansion of Eq. (1) yields the quadratic form

$$F=\int\left[A(\mathbf{r})\{\nabla\mathbf{m}\}^2+K_1(\mathbf{r})\mathbf{m}^2+\frac{1}{2}\mu_0 M_0(\mathbf{r})H\mathbf{m}^2\right]d\mathbf{r}. \tag{6}$$

Recall that K_2 and K_3 do *not* enter this expression,[19] so the nucleation field of ideally anisotropic hard magnets depends on K_1 only. The case of partially anisotropic and isotropic magnets will be discussed in Sec. IV. The equation of state $\delta F/\delta\mathbf{m}(\mathbf{r})=0$ is given by the identity

$$\frac{\delta F}{\delta\mathbf{m}(\mathbf{r})}=-\nabla\left(\frac{\partial\eta}{\partial\nabla\mathbf{m}(\mathbf{r})}\right)+\frac{\partial\eta}{\partial\mathbf{m}(\mathbf{r})}, \tag{7}$$

and reads

$$A(\mathbf{r})\nabla^2\mathbf{m}+\nabla A(\mathbf{r})\nabla\mathbf{m}-[2K_1(\mathbf{r})+\mu_0 M_0(\mathbf{r})H]\mathbf{m}=0. \tag{8}$$

Except for the $\nabla A(\mathbf{r})\nabla\mathbf{m}$ term (see Sec. IV), Eq. (8) is equivalent to Schrödinger's equation for a particle moving in a three-dimensional potential $2K_1(\mathbf{r})+\mu_0 M_0(\mathbf{r})H$, which allows us to apply ideas familiar from quantum mechanics to discuss micromagnetics. Note that the x and y components of $\mathbf{m}=m_x\mathbf{e}_x+m_y\mathbf{e}_y$ are decoupled and degenerate in Eq. (8), so the vector $\mathbf{m}(\mathbf{r})$ can be replaced by any unspecified nucleation mode $\Psi(\mathbf{r})$. It is, however, convenient to think of $\Psi(\mathbf{r})$ as the magnetization $m_x(\mathbf{r})$ in x direction.

Finally, for our inhomogeneous two-phase magnets we assume that the $\mathbf{r}$ dependence of the parameters A, K_1, and M_0 is given by A_h, K_h, M_h, and A_s, K_s, M_s for hard (index h) and soft (index s) regions, respectively. Let the volume fraction of the hard regions become f_h; the fraction of the soft regions is then given by $f_s=1-f_h$.

The nucleation field H_N is obtained as lowest eigenvalue of the Eq. (8). In the homogeneous "constant-potential" case, the ground-state eigenfunction is a plane wave with $\mathbf{k}=0$, and Eq. (8) reduces to the familiar form $H_N=-H=2K_1/\mu_0 M_0$. In the case of inhomogeneous magnets, the nucleation problem Eq. (8) can be solved by series expansion or an appropriate ansatz, which has been done for special one-, two-, and three-dimensional configurations.[17,19,24–27] An example is a spherical soft inclusion (diameter D, $K_s=0$) in a hard-magnetic matrix (cf. Fig. 1). Introducing spherical coordinates and using the interface boundary condition $A_s(\mathbf{e}\cdot\nabla)\Psi_s=A_h(\mathbf{e}\cdot\nabla)\Psi_h$ we obtain the eigenvalue equation[17]

$$\frac{A_s}{A_h}\left\{\frac{D}{2}\sqrt{\frac{\mu_0 M_s H_N}{2A_s}}\cot\left(\frac{D}{2}\sqrt{\frac{\mu_0 M_s H_N}{2A_s}}\right)-1\right\}+1 + \frac{D}{2}\sqrt{\frac{2K_h-\mu_0 M_h H_N}{2A_h}}=0, \tag{9}$$

which can be solved numerically. It turns out that the nucleation field reaches a high-coercivity plateau if the size of the soft inclusion is smaller than the Bloch wall thickness $\delta_h=\pi(A_h/K_h)^{1/2}$ of the hard phase. This plateau corresponds to complete exchange coupling. If the diameter D of the soft inclusion is too large, then the magnetization becomes unstable and the coercivity falls off as $1/D^2$.

For sufficiently small reverse fields $|H|<H_N(D)$ the single soft inclusion is perfectly aligned and slightly enhances the remanence provided $M_s>M_h$. On the other hand, when the distance between the soft inclusions is small, the magnetization modes can "tunnel" through the hard region which no longer acts as an effective potential barrier. In fact, this micromagnetic "exchange interaction" can reduce the nucleation field considerably when the thickness of the hard region is less than δ_h. To obtain physically reasonable nucleation fields, the complete $A(\mathbf{r})$, $K_1(\mathbf{r})$, and $M_0(\mathbf{r})$ profiles have to be taken into account.

IV. RESULTS

A. Coercivity

1. Plateau limit

In the plateau region, where the soft regions are very small, the problem can be treated in perturbation theory.[3,17,18] As in quantum mechanics, the lowest order eigenvalue correction is obtained by using the normalized unperturbed function Ψ_0. This yields the nucleation field

$$H_N=2\frac{f_s K_s+f_h K_h}{\mu_0(f_s M_s+f_h M_h)}. \tag{10}$$

Note that this result is independent of the shape of the soft and hard regions so long as the hard regions remain aligned.

2. Multilayer limit

It is comparatively easy to treat one-dimensional structures such as multilayers,[27] since the micromagnetic multilayer problem is analogous to the periodic multiple quantum well problem. For a multilayered structure of alternating soft and hard magnetic layers the nucleation field is given by the implicit equation[17]

$$\sqrt{\frac{2K_h-\mu_0 M_h H_N}{2A_h}}\tanh\left(\frac{l_h}{2}\sqrt{\frac{2K_h-\mu_0 M_h H_N}{2A_h}}\right) = \frac{A_s}{A_h}\sqrt{\frac{\mu_0 M_s H_N}{2A_s}}\tan\left(\frac{l_s}{2}\sqrt{\frac{\mu_0 M_s H_N}{2A_s}}\right), \tag{11}$$

where l_h and l_s denote the thicknesses of the hard and soft layers, respectively. Note, that this result does not depend on whether the orientation of the crystallographic c axis of the hard phase is perpendicular or longitudinal.

B. Energy product

Equation (10) implies an ideally rectangular hysteresis loop with energy product $\mu_0 M_r^2/4$, remanence $M_r = f_h M_h + f_s M_s$, and (minimum) coercivity $H_N = M_r/2$. Putting $K_s = 0$ in the plateau limit we obtain with $H_N = M_r/2$ the maximum energy product

$$(BH)_{\max} = \frac{1}{4}\mu_0 M_s^2 \left(1 - \frac{\mu_0 (M_s - M_h) M_s}{2K_h}\right). \tag{12}$$

Due to the large K_h, the second term in the bracket is small so the energy product approaches the ultimate value of $\mu_0 M_s^2/4$. The corresponding volume fraction of the hard phase is $f_h = \mu_0 M_s^2/4K_h$.

The intermetallic with the most favorable combination of magnetization and anisotropy is $Sm_2Fe_{17}N_3$. If we consider the $Sm_2Fe_{17}N_3/Fe$ system and assume values $\mu_0 M_s = 2.15$ T, $\mu_0 M_h = 1.55$ T, and $K_h = 12$ MJ/m^3, we obtain a theoretical energy product of 880 kJ/m^3 (110 MGOe) for a volume fraction of only 7% of the hard phase.[17] A further increase of the energy product is possible if iron is replaced by $Fe_{65}Co_{35}$ with $\mu_0 M_s = 2.43$ T—the theoretical energy product of the $Sm_2Fe_{17}N_3/Fe_{65}Co_{35}$ system might be as high as 1090 kJ/m^3 (137 MGOe), with $f_h = 9\%$. It is remarkable that these optimum magnets are almost entirely composed of $3d$ metals, with only about 2-wt % samarium.

Another possibility is a multilayered structure of alternating soft and hard magnetic layers. Assuming $A_s = 1.67 \times 10^{-11}$ J/m and $A_h = 1.07 \times 10^{-11}$ J/m we deduce from Eq. (11) that a $Sm_2Fe_{17}N_3/Fe_{65}Co_{35}$ "megajoule magnet" is obtained for layer thicknesses $l_h = 2.4$ nm and $l_s = 9.0$ nm. The macroscopic shape of the magnet must of course correspond to the optimum operating point on the BH curve; it should approximate an ellipsoid with c/a=0.55. Note that A is generally of order 10^{-11} J/m, so H_N and $(BH)_{\max}$ do not depend very much on the exchange-stiffness inhomogenity.

C. Texture

As we have seen, $K_2(\mathbf{r})$ and $K_3(\mathbf{r})$ do not influence the nucleation field so long as the unit vector in the easy axis direction $\mathbf{n}$ remains parallel to the field $\mathbf{e}_z$. The situation becomes much more difficult when the hard regions are only partially aligned or even isotropic. For instance, the components m_x and m_y of $\mathbf{m}$ [cf. Eq. (8)] are now coupled in a very complicated way. However, in lowest order perturbation theory the m_x and m_y decouple, and after some calculation we find that K_1 in Eq. (8) has to be replaced by

$$K_{\text{eff}} = -\tfrac{1}{2}(K_1 + 2K_2 + 4K_3) + \tfrac{3}{2}(K_1 + 4K_2 + 9K_3)\langle n_z^2\rangle - \tfrac{5}{2}(2K_2 + 9K_3)\langle n_z^4\rangle + \tfrac{21}{2} K_3 \langle n_z^6\rangle. \tag{13}$$

The ensemble average is defined as $\langle \ldots \rangle = \Omega^{-1} \int \ldots f(\theta) \sin\theta d\theta$ where $f(\theta)$ denotes the texture function of the hard phase. Note that Eq. (13) reduces to $K_{\text{eff}} = K_1$ in the ideally anisotopic limit $n_z = 1$.

To discuss the overall behavior of K_{eff} we use the single-parameter texture function $f(\theta) = (1+\nu)\cos^\nu \theta$[28] and restrict ourselves to the case $K_2 = K_3 = 0$. Using $n_z = \cos\theta$ we obtain

$$K_{\text{eff}} = K_h \left(\frac{2M' - M_h}{2M_h - M'}\right), \tag{14}$$

where M' is the remanence of the hard regions in the interaction-free limit, i.e., $M' = M_h$ for ideally anisotropic magnets and $M' = 0.5\, M_h$ for isotropic magnets. In lowest order perturbation theory the nucleation field is proportional to K_{eff}, so $H_N = 0$ for $M' = 0.5\, M_h$ in this approximation. This means, that the nucleation field vanishes in the isotropic limit if soft and hard regions are extremely small. An alternative interpretation is given by Eq. (12), where K_h has to be replaced by K_{eff}. The smallness of the $1/K_h$ correction term in Eq. (12) requires the effective anisotropy to be very large,[29] which is contradictory to $K_{\text{eff}} = 0$, and it is not possible to apply Eq. (12) to isotropic materials.

D. Isotropic magnets

In the case of an isotropic matrix with randomly oriented hard regions alternative methods have to be used to calculate the coercivity. An estimate is obtained from a simple model where two hard regions with $\mathbf{n}_1 = \mathbf{e}_z$ and $\mathbf{n}_2 = \pm\mathbf{e}_x$ are subject to an effective coupling A/R_{eff}^2. As it can be shown easily, the weak-coupling limit (isolated grains) yields $M_r = M_h/2$. In the case of strong exchange coupling the orientation of the grains is given by $\mathbf{s}_1 \approx \mathbf{s}_2 \approx \mathbf{e}_x/\sqrt{2} + \mathbf{e}_z/\sqrt{2}$, which yields the enhanced remanence $M_r = M_h/\sqrt{2}$. Note that the instability of the aligned $\mathbf{M}(\mathbf{r}) = M_h \mathbf{e}_z$ state implies $M_r < M_h$ for remanence-enhanced single-phase magnets.

On the other hand, exchange coupling destroys coercivity. For weak coupling we find $H_c = 2K_h/\mu_0 M_h$, while the strong-coupling coercivity $H_c = K_1^2 R_{\text{eff}}^2 (\sqrt{2}\mu_0 M_h A)^{-1}$ decreases with increasing exchange interaction. As expected, this result reduces to $H_c = 0$ in the "plateau limit" (infinitely large A or infinitely small R_{eff}).

V. DISCUSSION

A. Performance and processing

A conceivable way to exploit the surplus anisotropy in modern rare-earth permanent magnets is to use aligned two-phase magnets where the hard phase acts as a skeleton which keeps the magnetization of the soft phase in the desired direction. Micromagnetic analysis shows that the nucleation field in suitable nanostructured materials is proportional to the volume-averaged anisotropy.

Equation (12), which represents a hardness expansion with respect to the small parameter $\mu_0(M_s - M_h)M_s/K_1$, predicts the energy product of aligned nanostructured two-phase magnets to be nearly as high as the ultimate value $\mu_0 M_0^2/4$. From the point of view of exchange coupling, the

mechanism is similar to the remanence enhancement in isotropic magnets, but yields a saturation magnetization which is larger than that of the aligned hard phase.

The practical problem is to realize a structure where the soft regions are sufficiently small to avoid nucleation at small fields while having the hard regions crystallographically oriented. One conceivable solution is a disordered two-phase magnet with a common c axis throughout the hard regions. The energy product Eq. (12) is independent of the shape of the soft regions, so long as their size lies in the plateau region. However, soft regions much larger than this plateau size drastically reduce the nucleation field,[29] and it is difficult to see how the formation of large soft-magnetic clusters might be avoided in practice. Furthermore, the hard skeleton has to be aligned to avoid the anisotropy reduction described by Eq. (14). Note that remanence-enhanced *isotropic* two-phase magnets operate on a slightly larger length scale.

A more realistic possibility may be a multilayered structure of alternating soft- and hard-magnetic layers. Conceivable production methods are laser ablation deposition[30] or molecular-beam epitaxy. As discussed in Sec. IV, the permanent-magnetic performance of the multilayer is independent of whether the hard phase is perpendicularly or longitudinally aligned. It is worthwhile mentioning that permanent magnetic multilayers are one-dimensional systems, whose eigenmodes are subject to weak localization (Anderson localization). Weak localization in one-dimensional systems is caused by an arbitrarily small disorder,[31,32] and second-order perturbation theory[29] yields zero coercivity if the disorder is described by Gaussian or Poisson correlations. The reason for this coercivity breakdown is the small but finite probability of thick soft layers, since the coercivity is determined by the thickest soft layer around which the nucleation mode is localized. This means that weak localization does not destroy coercivity if there is an upper limit to the thickness of the soft layers.

Equation (1) is based on classical micromagnetic considerations; the sizes of the hard and soft regions must be large compared to atomic dimensions so that a continuum model can be applied. The model must break down when l_s or l_h is smaller than about 1 nm. However, due to the small prefactor $(M_s-M_h)/M_s$, 0.28 for the $Sm_2Fe_{17}N_3$/Fe system, the energy product is not much affected if the fraction of the hard phase is increased. We still have an energy product of almost 800 kJ/m^3 (100 MGOe) in the $Sm_2Fe_{17}N_3$/Fe system when $f_h \approx 30\%$, and we can use the extra hard material to outweigh quantum-mechanical size effects, to improve the thermal stability, suppress the effect of random stray fields and to create pinning centers.[17,29]

B. Outlook

Table I gives a tentative discussion of the question to what extent "giant-energy product" magnets will ever be exploited commercially. At present, the actual production of these structures represents a realistic but nevertheless extremely demanding challenge. In other words, the advantages of hypothetical "megajoule" magnets—very high energy product and low raw material costs—are largely outweighed by the complicated processing requirements. We therefore believe that the use of aligned nanostructured two phase magnets will be restricted to special applications such as micromechanics or thin-film electronics.

TABLE I. Permanent magnet processing and applications.

Material	Performance	Processing costs	Raw material price
Steel	low	low	low
Ferrites	moderate	moderate	low
$SmCo_5$	high	moderate	high
$Nd_2Fe_{14}B$	high	moderate	moderate
$Sm_2Fe_{17}N_3$	high	high	moderate
"MJ" magnets	very high	very high	low

Of course, this emphasis on processing is likely to be a feature of all future permanent magnets, even if we include "exotic" systems such as magnetically hard room-temperature superconductive currents or nanoscale magnetic clusters where the $>$ sign in Eq. (4) can be utilized.[9] Let us imagine, for example, that it is possible to produce a single-phase permanent magnet somewhat better than $Nd_2Fe_{14}B$ by quenching from a high-pressure equilibrium state. The processing of this material will almost certainly be much more expensive than that of $Nd_2Fe_{14}B$, leading to much less widespread commercial applications. In our opinion, singular events such as the discovery of $Nd_2Fe_{14}B$ are unlikely to happen again, and most future technological and scientific progress will be in directions other than improving the energy product.

VI. CONCLUSIONS

In conclusion, it is likely that substantial improvements in the energy product of permanent magnets can be achieved by exchange hardening in nanoscale combinations of a soft phase and an oriented hard phase, structured according to the principles we have outlined. For example, the maximum energy product of nanostructured $Sm_2Fe_{17}N_3/Fe_{65}Co_{35}$ multilayers is predicted to be as high as 1090 kJ/m^3 (137 MGOe). The high energy product, which is based on nucleation-controlled coercivity, breaks down in the limit of remanence-enhanced isotropic magnets. The actual production of the new material—a demanding but realistic aim—will be expensive, which restricts the potential use of 'giant-energy-product' magnets to special applications.

We have studied the crystallization, crystal structure, microstructure and magnetic properties of R-Fe-B (R=Nd,Pr,Dy,Tb) based melt-spun ribbons consisting of a mixture of $R_2Fe_{14}B$ and α-Fe phases. All the samples crystallize first to α-Fe and a metastable phase ($Y_3Fe_{62}B_{14}$ for R=Nd,Pr,Dy and $TbCu_7$ for R=Tb) before they finally transform to 2:14:1 and α-Fe. The highest values of coercivity and reduced remanence, 4.5 and 0.63 kOe, respectively, were obtained in a $Nd_{3.85}Tb_2(Fe\text{-}Nb\text{-}B)_{94.15}$ sample. These properties are the result of a fine grain microstructure consisting of a mixture of α-Fe and 2:14:1 having an average grain size of 30 nm.

INTRODUCTION

A high reduced remanence (M_r/M_s), greater than 0.5, in isotropic magnets is highly desirable for permanent magnet development. Remanence enhancement has been observed previously in isotropic $Nd_2Fe_{14}B$ magnets with small Al and Si substitutions,[1,2] and more recently,[3] in samples with a controlled microstructure. High values of magnetization and reduced remanence can also be achieved in samples with a microstructure consisting of a fine mixture of hard (high anisotropy) and soft (higher magnetization) phases.[4,5] Kneller and Hwaig[6] have shown that high remanence and relatively high coercivity could be expected in a fine two-phase microstructure where the small grains are exchange-coupled.

Previously, we have studied various mixtures of $Nd_2Fe_{14}B$ and α-Fe and observed a maximum coercivity of 4.0 kOe along with a remanent magnetization of 110 emu/g in a 50 wt % 2:14:1 and 50 wt % α-Fe mixture.[7] In this report, we extend our studies on nanocomposite magnets to other rare earth 2:14:1 phases.

EXPERIMENT

$R_x(Fe\text{-}Nb)_yB_z$ ingots with different composition with R=Nd, Pr, Dy and Tb ($4<x<6$, $88<y<93$, $4<z<6$) were prepared by arc melting the constituent elements in an argon atmosphere. Pieces of the ingot were melt-spun from a quartz tube having an orifice diameter of ~1 mm. A wheel speed in the range of 25–45 m/s was used. The resulting ribbons were studied using differential scanning calorimetry (DSC) and differential thermal analysis (DTA) for possible phase transformations. X-ray diffraction (Cu K_α) was used to identify the phases present. The hysteresis loops were measured in a vibrating sample magnetometer (VSM) with a maximum field of 20 kOe on long (7 mm) sample pieces to minimize demagnetization effects. Selected samples were also measured in a SQUID magnetometer with a maximum field of 55 kOe. The microstructure of samples having different coercivities was studied by transmission electron microscopy (TEM) using a Jeol JEM 2000FX.

RESULTS AND DISCUSSION

The melt-spun ribbons were found to be x-ray amorphous (or nanocrystalline) in structure. Calorimetric studies were performed on the as-spun samples using DSC and DTA to obtain transition temperatures, latent heats, and activation energies. Typical thermal scans consisting of two or more exothermic peaks are shown in Fig. 1 for Nd-Fe-B and Dy-Fe-B based samples. The first exotherm involves a latent heat of about 70–80 J/g along with activation energies in the range 280–380 kJ/mol (see Table I). The latter quantity was evaluated by plotting ln (rate/T_p) vs $1/T_p$ for different heating rates where T_p denotes the temperature of maximum transform.[8,9] In the case of Nd, Pr, Dy this exotherm corresponds to the transformation from amorphous to metastable $Y_3Fe_{62}B_{14}$ type structure in addition to α-Fe [see Fig. 2(a)]. Similar studies on Tb-Fe-B ribbons show a transition from amorphous to hexagonal $TbCu_7$-type structure and α-Fe. Structural information and the Curie temperatures of these metastable compounds are summarized in Table II. When the samples were heat treated at temperatures above the highest transition temperature, the metastable $Y_3Fe_{62}B_{14}$ structure was found to transform to 2:14:1 + α-Fe and the $TbCu_7$ structure to a mixture of 2:14:1, α-Fe, and probably to 2:17 phases as determined by x-ray diffraction. The temperature associated with the formation of 2:14:1 phase is higher in the samples with Tb or Dy.

TABLE I. Transformation temperatures (T_i) and activation energies (E_i) associated with the phase transformations in R_6 (Fe-Nb-B)$_{94}$ ribbons (see text and Table II for details).

R	T_1 (°C)	E_1 (kJ/mol)	T_2 (°C)	E_2 (kJ/mol)
Nd	586	388	734	456
Pr	572	374	720	472
Dy	587	312	827	381
Tb	594	289	811	455

TABLE II. Structure type, lattice parameters and Curie temperatures of the phases formed after the first crystallization of R_6(Fe-Nb-B)$_{94}$ ribbons.

R	Structure type	a (nm)	c (nm)	T_c (°C)
Nd	bcc $Y_3Fe_{62}B_{14}$	1.231	...	200
Pr	same	1.234	...	200
Dy	same	1.235	...	210
Tb	hex. $TbCu_7$	4.801	4.225	240

The intensity distribution among the 2:14:1 peaks in these ribbon samples is similar to that of a $R_2Fe_{14}B$ powder diffraction pattern indicating the isotropic nature of the samples [Fig. 2(b)]. This was further confirmed by hysteresis loop measurements carried out along and transverse to the ribbon length.

Large coercivities were observed in the samples after annealing above the higher temperature (T_2 in Table I) exothermic peak. By varying the annealing temperature and time these coercivities were optimized. Hysteresis loops of two samples with optimum coercivity are shown in Fig. 3. Although these samples consist of two or more magnetic components, the smooth hysteresis loops are characteristic of a single component system but with high remanence values. The observation of high reduced remanence ($M_r/M_s>0.5$) and reversible demagnetization curves in these isotropic samples[7] indicates the behavior of exchange-coupled magnets.[6]

The highest coercivity of 4.5 kOe was observed in a sample containing a mixture of rare-earths ($Nd_{3.85}Tb_2$) compared to 4.0 kOe in the pure $Nd_{5.85}$(Fe-Nb-B)$_{94.15}$ sample. The slight asymmetry in these loops is believed to be a consequence of lack of saturation. However, the introduction of Tb lowers the magnetization of these ribbons from 155 emu/g in $Nd_{5.85}$(Fe-Nb-B)$_{94.15}$ to 130 emu/g. In Pr_6(Fe-Nb-B)$_{94}$ ribbons a maximum coercivity of 3.9 kOe and a remanent magnetization of 105 emu/g were observed. The coercivity of the pure Tb(Dy) samples is much lower (~1 kOe) despite the high anisotropy of the $R_2Fe_{14}B$ (R =Tb,Dy) phases. This is attributed to the formation of larger grains in these samples because of the higher annealing temperatures necessary to form the hard $R_2Fe_{14}B$ phase.

The values of the coercivities given previously correspond to a maximum magnetizing field of 20 kOe. To check whether the loops were not minor, higher magnetizing fields were used and the results are shown in Fig. 4 for the sample with largest coercivity. The coercive force does not saturate

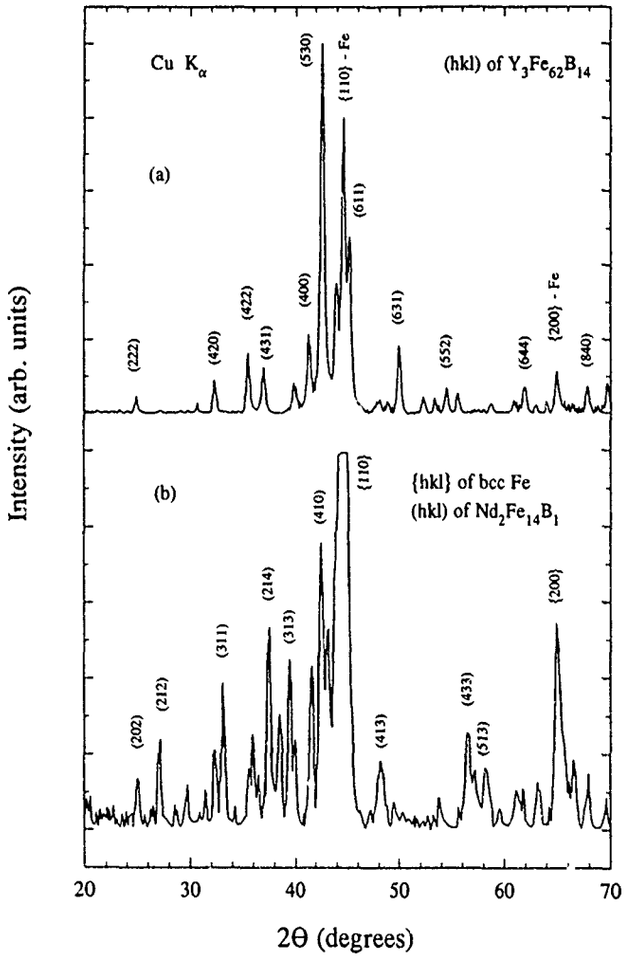

FIG. 2. X-ray diffraction patterns showing the (a) $Y_3Fe_{62}B_{14}$ and α-Fe structures and (b) $R_2Fe_{14}B$ + α-Fe observed in R_6(Fe-Nb-B)$_{94}$ ribbon samples with R=Nd, Pr, and Dy.

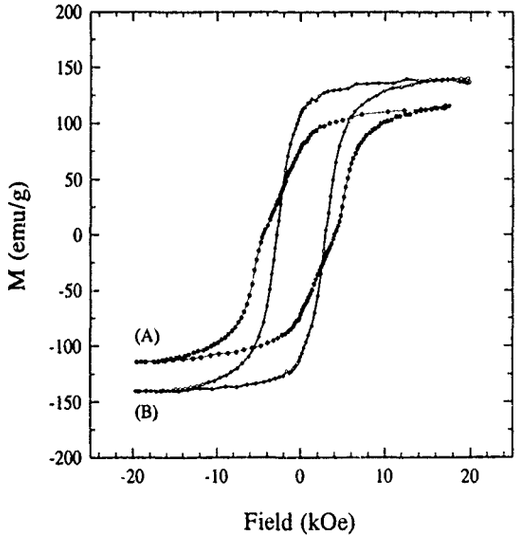

FIG. 3. Hysteresis loops of the coercivity optimized (A) $Nd_{3.85}Tb_2$(Fe-Nb-B)$_{94.15}$ and (B) $Nd_{3.2}Tb_1$(Fe-Nb-B)$_{95.8}$ samples.

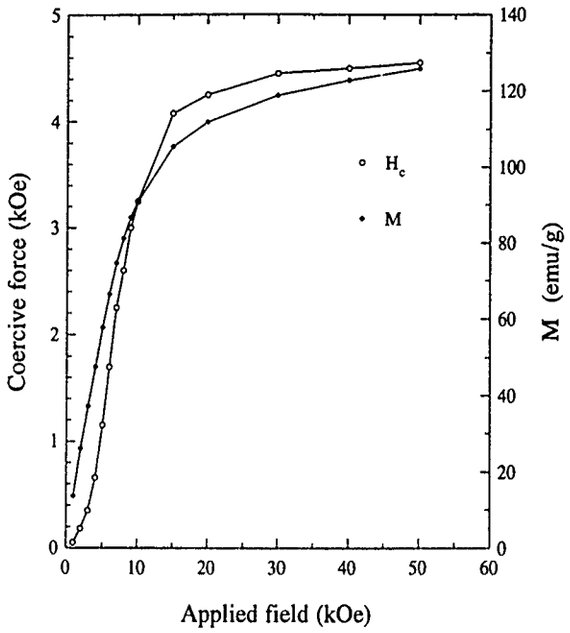

FIG. 4. The dependence of coercive force and magnetization on magnetizing field in a $Nd_{3.85}Tb_2(Fe\text{-}Nb\text{-}B)_{95.15}$ sample

for magnetizing fields lower than 30 kOe and the magnetization has a high field slope indicating lack of saturation.

Transmission electron microscopy was carried out to study the microstructure in samples exhibiting different coercive behavior. Figure 5 shows the bright-field images of two $Nd_6(Fe\text{-}Nb\text{-}B)_{94}$ samples annealed at 700 °C for 20 and 120 min. The samples annealed for a shorter period of 20 min showed a microstructure [Fig. 5(a)] consisting of a homogeneous mixture of α-Fe and 2:14:1 phases with an average grain size of about 30 nm. The hysteresis loops in the samples were similar to that of a single magnetic component. In samples annealed for 120 min, a microstructure consisting of clusters of α-Fe was observed in a matrix of 2:14:1 phase [Fig. 5(b)]. The hysteresis loops in these samples were representative of a two-component system.

CONCLUSIONS

The magnetic, structural, and microstructural properties of R-Fe-B based nanocomposite ribbons with R=Nd, Pr, Dy and Tb have been studied. A room-temperature coercivity of 4.5 kOe was observed in a sample containing Nd and Tb as compared to 4.0 kOe in the pure Nd samples. The optimum microstructure consists of a uniform mixture of 2:14:1 and α-Fe grains of about 30 nm. The coercivity of pure Tb or Dy samples is only in the 1 kOe range presumably due to the larger grains formed at the higher annealing temperatures (because of the higher transformation temperatures) associated with these alloys.

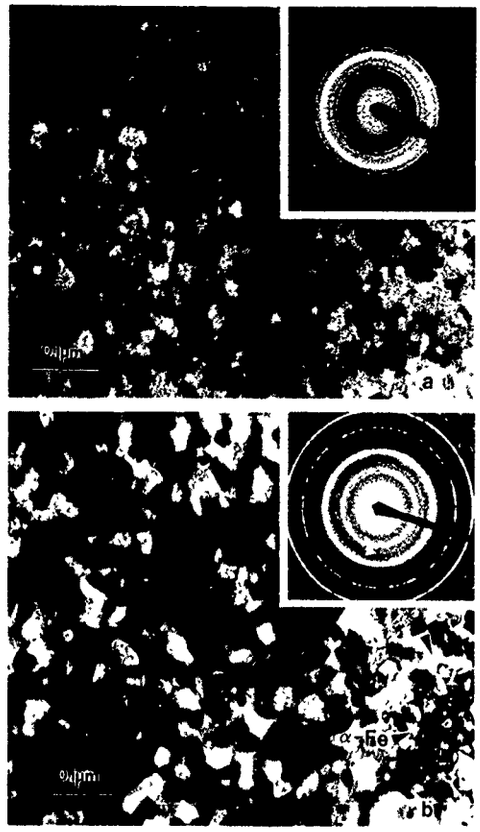

FIG. 5. Bright-field images in a $Nd_6(Fe\text{-}Nb\text{-}B)_{94}$ sample annealed at 700 °C for (a) 20 min, and for (b) 120 min. The diffraction patterns indicate a mixture of 2:14:1 and α-Fe phases

In nanostructured $Sm_2Fe_{17}N_x+\alpha$-Fe two-phase permanent magnets, exchange interactions between hard and soft magnetic phases result in remanence enhancement. With a starting composition of Sm_7Fe_{93}, mechanical alloying, annealing at 625 °C for 10 min and subsequent nitriding at 330 °C for 45 h results in hard magnetic powder with nanocrystallites of $Sm_2Fe_{17}N_3$ and α-Fe some 20 nm in size. There is a coercivity of $\mu_0 H_c = 0.4$ T and a remanence $J_r = 1.2$ T, after saturating in a field of 7.5 T. The deduced value of the remanence depends strongly on the choice of demagnetizing factor.

INTRODUCTION

Since the discovery of remanence enhancement in isotropic nanocrystalline $Nd_{4.5}Fe_{77}B_{18.5}$ in 1988 by Coehoorn *et al.*,[1] there has been much experimental and theoretical interest in this phenomenon. The idea of transmitting anisotropy by exchange coupling of hard and soft phases (the "exchange spring") was proposed by Kneller and Hawig.[2] There have been a number of papers on analytical calculations[3] and computer simulations[4] of these exchange hardened two-phase materials. Recent progress has been made to produce bonded magnets using the $Nd_{4.5}Fe_{77}B_{18.5}$ composition from melt spun ribbon realizing coercivities, $\mu_0 H_c$ of 0.36–0.44 T with remanences J_r of 0.89–0.80 T.[5]

The original material, $Nd_{4.5}Fe_{77}B_{18.5}$ consisted of exchange coupled grains of $Nd_2Fe_{14}B$, Fe_3B, and α-Fe in the ratio 15, 73, and 12 with crystallite sizes ranging from 10 to 30 nm. Related behavior is found in nanocrystalline, single phase, $Nd_2Fe_{14}B$ where the addition of 2 at. % Si refines the grain size to 20–30 nm.[6] Si is not a specific requirement,[7] as under certain processing conditions, which yield a grain size of 20–30 nm, a similar remanence enhancement could be obtained. This type of remanence enhancement has also been modeled using a computer simulation.[8]

Coercivities of 3 T have been obtained in $Sm_2Fe_{17}N_3$ produced by mechanical alloying,[9] but due to the isotropic nature of this nanocrystalline material the remanence was limited to a value of 0.75 T, half the saturation magnetization. Due to the rather low decomposition temperature of the $Sm_2Fe_{17}N_3$ phase (600 °C) it is not possible to apply the die upsetting method used in $Nd_2Fe_{14}B$ to produce anisotropy.

In 1993 Ding *et al.*[10] showed that a nanocrystalline two-phase mixture of $Sm_2Fe_{17}N_x$ and α-Fe produced by mechanical alloying exhibited remanence enhancement. The isotropic powders have $J_r = 1.4$ T and $\mu_0 H_c = 0.39$ T.

Theoretical modeling of such two-phase nanocrystalline materials, where a high magnetization soft phase is exchange coupled to a high anisotropy hard phase has yielded insight into the critical grain sizes and grain boundary requirements. To preserve coercivity in the nanocomposite, the size of the soft grains must be sufficiently small. The relevant length scale is the domain wall width of the hard phase. The analytical results of Skomski and Coey[3] and the computer simulations of Schrefl *et al.*[4] show that the size of the magneti-

[a]*UN*=before nitriding−unnitrided.

cally soft region should be roughly twice the domain wall width of the hard phase to stiffen the soft magnetic grains.

The domain wall width depends on the anisotropy according to the well-known formula $\delta_w = \pi(A/K_1)^{1/2}$. In the $Sm_2Fe_{17}N_x$ system, the anisotropy constant K_1 and the exchange parameter A increase with nitrogen content up to $x=3$.[11] Values for $x=3$ are $A=1.1\times10^{-11}$ J/m and $K_1=8$ MJ/m^3.[12] Here we investigate the influence of the nitriding conditions on the overall magnetic properties of two-phase exchange-hardened $Sm_2Fe_{17}N_x+\alpha$-Fe.

EXPERIMENT

Elemental Sm and Fe were mechanically alloyed in the ratio Sm_7Fe_{93} in a planetary ball mill. 20 g of the starting mixture was placed in hardened stainless-steel vials together with 400 g of 10-mm-diam stainless-steel balls. The as-milled powders were annealed at 625 °C for 10 min under vacuum. The subsequent nitriding was carried out in 1 bar of N_2 at 330 °C for times ranging from 5 to 64 h. Structural investigations were performed with a Siemens D500 x-ray diffractometer using Cu K_α radiation. The nanostructure of this two phase exchange-hardened material was characterized by transmission electron microscopy. Magnetization measurements were performed on powder samples dispersed in resin, with a packing density of about 30%, in a vibrating sample magnetometer in applied fields up to 7.5 T.

RESULTS AND DISCUSSION

The as-milled powders consisted of crystallites of α-Fe embedded in an amorphous matrix of Sm-Fe. Scherrer broadening of the x-ray reflections indicated these crystallites to be between 5 and 10 nm in size. Following crystallization of the Sm_2Fe_{17} phase there was a mixture of Sm_2Fe_{17} and α-Fe in the ratio 60:40 as determined from measurements of the saturation magnetization. Initially nitriding was carried out using 1 bar of N_2 at 400 °C for 2 h followed by 1 h at 475 °C. This resulted in a powder with a coercivity of 0.28 T. The weight gain on nitriding indicated complete nitrogenation. The nitriding temperature was then reduced to 330 °C and the time increased to 5 h. This yielded a better coercivity of 0.35 T even though both the weight gain and the x-ray diffraction pattern, shown in Fig. 1 suggest incomplete nitrogenation. The reason for the much improved results at the lower nitriding temperature of 330 °C is not yet clear. Using the formula for an activated interstitial diffusion process, $D=D_0\exp-(E_a/kT)$ with $D_0=1.02\times10^{-6}$ m^2/s and an activation energy $E_a=133$ kJ/mol,[13] the diffusion length for a temperature of 330 °C and a time of 5 h, is approximately 200 nm which is much less than the particle size (1–100 μm with an average of 20 μm) but greater than the size of the nanocrystallites which are only 20 nm in diameter. This suggests that nitrogen diffusion advances rapidly along the Sm_2Fe_{17}/Fe grain boundaries, but 5 h is insufficient to achieve complete nitrogenation of the particles.

Keeping a nitriding temperature of 330 °C samples were then nitrided for time periods of 24, 45, and 64 h and the

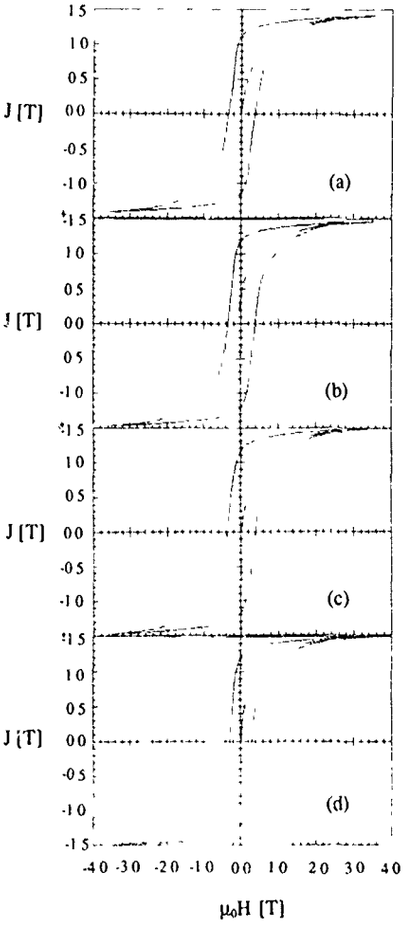

FIG. 2. Hysteresis loops of mechanically alloyed Sm_7Fe_{93}, annealed at 625 °C for 10 min after nitriding in 1 bar of nitrogen at 330 °C for (a) 5 h, (b) 24 h, (c) 45 h, and (d) 64 h.

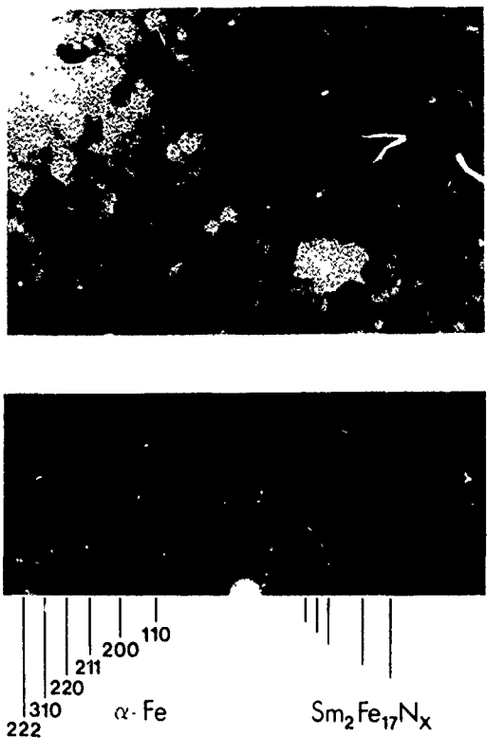

FIG. 3. (a) TEM bright-field micrograph of mechanically alloyed Sm_7Fe_{93} annealed at 625 °C for 10 min and nitrided in 1 bar of N_2 at 400 °C for 2 h followed by 1 h at 475 °C. (b) Electron diffraction pattern corresponding to the area in (a).

results are presented in Table I and Fig. 2. From the lattice parameters in Table I, it appears that after a nitriding treatment in 1 bar of N_2 at 330 °C for 24 h, the powder is completely nitrided. The coercivity increases from 0.36 to 0.38 T after nitrogenation at 330 °C for 45 h. Longer nitriding time leads to further increase in the lattice expansion, which may result from a value of x in the formula $Sm_2Fe_{17}N_x$, slightly greater than 3. The decrease in anisotropy field for $x>3$ (Ref. 14) is a possible explanation for the fall in coercivity from 0.38 to 0.29 T.

The coercivity and remanence values given in Table I were obtained in a field of 3.5 T. The A coercivity of 0.38 T increases to 0.40 T in a 7.5 T field. Remanence values are calculated using the theoretical powder density of 7.7 g/cm^3. In correcting the hysteresis loops of resin bonded powder samples for demagnetizing fields it is not sufficient to use the correction factor appropriate to the external shape of the sample. Due to the low packing density, there are internal demagnetizing fields which need to be taken into account. Samples measured in closed circuit using a BH loop tracer indicated strong internal demagnetizing fields, thus in each case a demagnetizing factor of 0.33 was used taking into account the roughly spherical shape of particles and the absence of magnetic interactions.

At annealing temperatures and times greater than 625 °C for 10 min, the hysteresis loop of the nitrided material showed a constriction, i.e., magnetic behavior indicative of two independent phases, one with a large coercivity and the other with a small coercivity. The α-Fe grains grow rapidly during annealing, and if they exceed a certain size the two phases tend to behave independently. Figure 3 shows a bright-field micrograph of the microstructure of an optimally annealed sample nitrided at 400 °C for 2 h followed by 475 °C for 1 h. Ultrafine grains with an average size of about 20 nm are visible. The electron diffraction pattern corresponding to that area is presented in the lower part of the figure. It reveals the presence of the two phases $Sm_2Fe_{17}N_x$ and α-Fe, which are both randomly oriented, indicated by the occurrence of complete diffraction rings. A high resolution image shows lattice fringes characteristic of the two phases.

The calculated domain wall width of $Sm_2Fe_{17}N_3$ is approximately 4 nm.[12] This implies that for most effective transfer of the hard magnetic properties to the soft magnetic grains, the size of the soft grains should not exceed approximately 8 nm. The milling and annealing conditions were systematically varied, but the end result, without the use of additions[15] was always that, the minimum size of the α-Fe grains after crystallization of the Sm_2Fe_{17} phase was about 20 nm. It should be investigated whether by lowering the anisotropy of the hard phase, $Sm_2Fe_{17}N_x$ by reducing x for example, the increase of the domain wall width δ_w would lead to a greater coercivity.

CONCLUSIONS

Complete nitrogenation at such a low temperature of the two-phase nanostructure is in contrast to that of nanocrystalline single phase $Sm_2Fe_{17}N_3$ prepared by a similar process. It suggests that nitrogen diffusion is particularly easy along Sm_2Fe_{17}/Fe grain boundaries. The activation energy for the diffusion of nitrogen in α-Fe is ~half that in Sm_2Fe_{17}. A homogeneous nanostructure is achieved by mechanical alloying, but the size of the soft, α-Fe regions is approximately 20 nm, which is about twice the size for optimum exchange hardening.

Coercivity of Ti-modified nanocrystalline (α-Fe)-$Nd_2Fe_{14}B$ alloys with soft iron particles embedded in hard $Nd_2Fe_{14}B$ matrix was studied. The alloys were prepared by melt spinning and annealing. The grain size of $Nd_2Fe_{14}B$ is from 20 to 60 nm, while that of the soft iron particles is 11 to 30 nm. The coercivity of the annealed flakes decreased dramatically with increasing particle size of free iron, following the same tendency of a theoretical calculation by Schrefl *et al.* For the Ti-alloyed flakes, the 1 at. % Ti-containing ones show the highest coercivity of 11.1 kOe. Its $(BH)_m$ value is about 16 MGOe despite lower Nd and B contents than stoichiometric $Nd_2Fe_{14}B$. More Ti addition would deteriorate the coercivity.

I. INTRODUCTION

Rapidly quenched Nd-Fe-B flakes with Nd and B richer than the stoichiometric $Nd_2Fe_{14}B$ (2-14-1) composition have been extensively studied.[1,2] The high coercivity and energy product of the flakes primarily results from the magnetically hard $Nd_2Fe_{14}B$ phase. Recently, some researchers proposed a kind of nanostructured two-phase magnets with soft magnetic phase embedded in hard magnetic phase.[3–5] This material has been attracting much attention because it possesses high saturation magnetization with moderate coercivity, hence the maximum energy product can be greatly enhanced. In this study, we intend to precipitate fine soft iron particles within $Nd_2Fe_{14}B$ matrix in the α-Fe/$Nd_2Fe_{14}B$ psuedobinary system. The alloying effect of Ti element was also systematically studied.

II. EXPERIMENT

The studied alloy compositions are designated as shown in Table I. The samples were prepared first by arc-melting Nd, Fe, B, Ti elements of +99.5% purity under argon protection, then remelted by induction melting and rapid quenching at a wheel speed (V_s) of 40 m/s by using single-roller melt-spinning technique.[6,7] The as-spun flakes were annealed at different temperatures from 600 to 800 °C for 10 min. Differential thermal analysis (DTA) was used to determine the crystallization temperature and activation energy of crystallization of as-spun flakes. Magnetic properties were measured by a VSM with a maximum field of 20 kOe at room temperature. The crystal structure of the flakes was studied by x-ray diffractometry (XRD) using Cu $K\alpha$ radiation. The grain size of free α-Fe was calculated from the full width at half maximum (FWHM) data by using Schererr's formula. The microstructure was studied using a transmission electron microscope (TEM) with an energy dispersive spectroscopy (EDS) attachment.

TABLE I The designation of the studied alloy composition.

$Nd_{10.58}Fe_{84.11}B_{5.29}Ti_x$	$Nd_9Fe_{86.5}B_{4.5}Ti_x$	$Nd_8Fe_{88}B_4Ti_x$
N10T0 ($x=0$)	N9T0 ($x=0$)	N8T0 ($x=0$)
N10T1 ($x=1$)	N9T1 ($x=1$)	N8T1 ($x=1$)
...	N9T2 ($x=2$)	N8T3 ($x=3$)

III. RESULTS AND DISCUSSION

A. Crystallization behavior of as-spun flakes

The as-melt-spun amorphous flakes can be obtained by high-speed melt spinning even though they contain low B and Nd contents. These flakes show a glass transition temperature (T_g) of around 470 °C and a crystallization temperature (T_x) of around 600 °C. The T_x value increases with increasing amount of α-Fe and Ti, as shown in Table II. The activation energy (E_a) of crystallization is calculated using the Kissinger plot.[8] The N8T3 flakes show a higher-energy barrier of crystallization than N10T1 flakes, which is consistent with the crystallization temperature datum.

B. Magnetic properties of annealed flakes

The Ti-1 at. % alloyed flakes annealed at 750 °C for 10 min show the highest-energy product with an improved squareness of the demagnetization curve. The $(BH)_m$ value of 15.9 MGOe is higher than that of conventional MQI (tradename of flakes manufactured by Magnetquench, typically 14–15 MGOe) despite its lower Nd and B contents than stoichiometric $Nd_2Fe_{14}B$.

Figure 1 shows the dependence of Nd content on coercivity. The intrinsic coercivity (iHc) value increases linearly with Nd content. The increasing rate of iHc is 2.5 kOe at. % Nd. But the B_r value increases as decreasing Nd content due to the enhanced remanence effect as predicted by the theory.[3] For the Ti-containing samples, iHc of the 1 at. % Ti added

TABLE II. Crystallization temperature (T_x) and activation energy (E_a). T_x was measured at a heating rate of 10 °C/min, E_a calculated from the peak shift in DTA curves obtained at heating rates of 5, 10, and 15 °C/min.

Alloy	N10T1	N9T2	N8T3
T_x(°C)	576	590	605
E_a (kJ/mole)	73	..	119

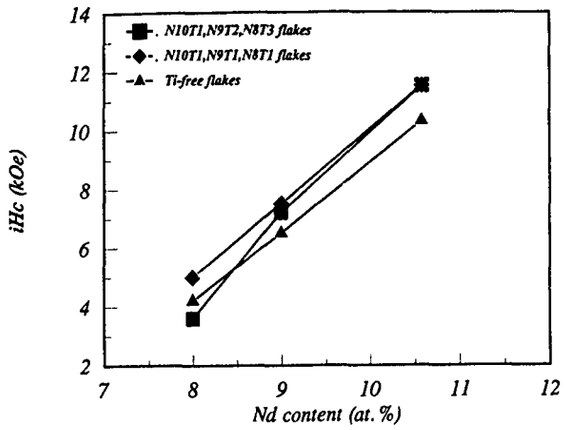

FIG. 1. Dependence of Nd content on iHc value of flakes annealed at 750 °C for 10 min.

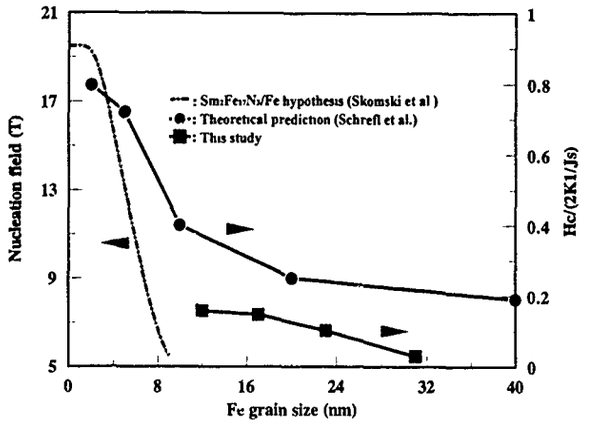

FIG. 3. Micromagnetic simulation (Ref. 5), Skomski's modeling (Ref. 3), and experimental data of the effect of α-Fe particle size on the coercivity of flakes annealed at 750 °C for 10 min.

samples is higher than Ti-free samples. However, more Ti addition would result in a rapid deterioration of iHc due to the growth of α-Fe. Figure 2 shows the effect of annealing temperature on iHc of the Ti-free, the 1% Ti and 2% Ti alloys. It is manifest that the optimum annealing temperature ranges from 700 to 750 °C. The optimum temperature increases with Ti content.

C. Microstructure features

The grain size of α-Fe is measured by the peak-broadening technique in XRD calibrated against a pure iron sample with large grains (about 10 μm). The coercivity of flakes decreased rapidly with increasing particle size of α-Fe precipitates. Figure 3 shows the relationship between α-Fe particle size and coercivity for the annealed Ti-containing flakes. The theoretical predictions proposed by Skomski and Coey[3] and Schrefl *et al.*[5] have delineated similar behavior, also shown in Fig. 3. There is a discrepancy between the experimental results and the theoretical calculation by Schrefl *et al.*[5] In the figure the normalized coercivity (normalized by the theoretical nucleation field, $2K_1/J_s$, of the hard magnetic phase) is twice as large as the experimental ones. This may arise from the fact that the theoretical modeling has the soft iron particles completely embedded within hard magnetic phase, while in the studied alloys, the free-iron particles are mostly free standing among $Nd_2Fe_{14}B$ grains and partly embedded (particularly for smaller ones), as shown in Fig. 4. Nevertheless, the tendency is correct that the coercivity does drop dramatically when α-Fe particles grow up. The comparison between the experimental results and Skomski's calculation is difficult because the size range is different.

Figure 4 is a TEM micrograph taken from N10T1 flakes annealed at 750 °C for 10 min. The flakes exhibit a fine grain structure with soft iron particles mostly free standing among and partly embedded in hard $Nd_2Fe_{14}B$ phase. The grain size of the $Nd_2Fe_{14}B$ phase ranges from 20 to 60 nm and the soft iron particles are generally less than 20 nm. It has proposed that fine $Nd_2Fe_{14}B$ grains significantly contribute to the coercivity by acting as the domain-wall-pinning sites. The free-iron particles are smaller than single domain, so when a domain wall sweep across it, large exchange anisotropy will be

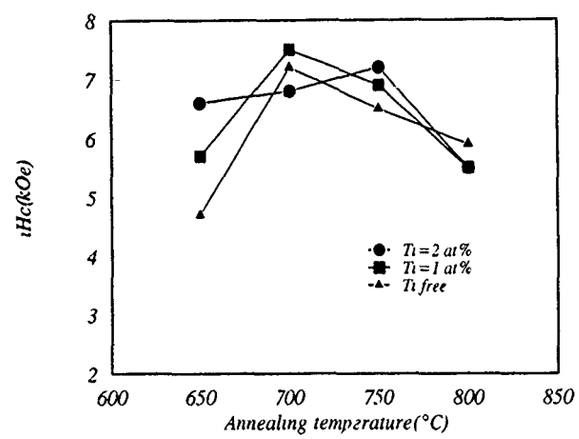

FIG 2. Annealing effect on the coercivity for $Nd_9Fe_{86.5}B_{4.5}Ti_x$ ($x=0-2$ at. %).

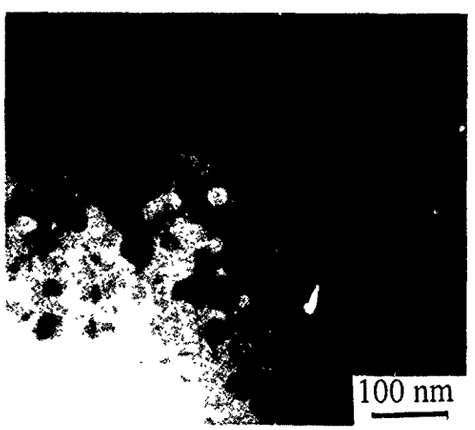

FIG. 4. TEM micrograph of a $Nd_{10.58}Fe_{84.11}B_{5.29}Ti$ flake annealed at 750 °C for 10 min.

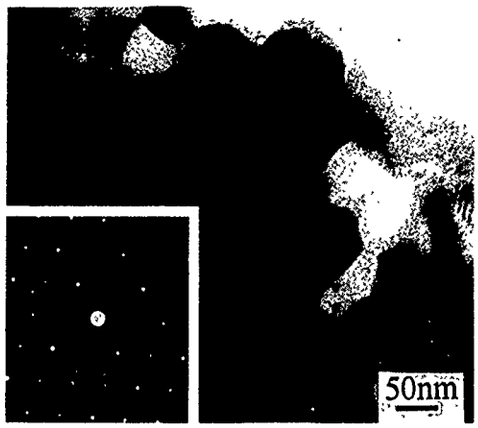

FIG. 5. A few larger grains found in annealed $Nd_{10.58}Fe_{84.11}B_{5.29}Ti$ flakes; inset is the SAD pattern showing the 2-14-1 phase.

encountered.[7] Similar results were also reported previously by Manaf *et al.*[4] When the particle size of α-Fe is further reduced, approaching the domain-wall width of hard $Nd_2Fe_{14}B$ phase, the exchange interaction would suppress the reversible rotation of magnetization in the soft iron particles and result in a significant rise of coercivity.[5] Figure 5 shows a few larger grains found in N10T1 flakes, probably due to a gas-pocket trapped between ribbon and wheel surface. The selected area diffraction pattern (the inset) of the larger grains demonstrates a $Nd_2Fe_{14}B$ phase structure. EDS analysis with an ultrafine electron probe (beam diameter ~10 nm) indicates that Ti atoms are homogeneously distributed between the $Nd_2Fe_{14}B$ matrix and α-Fe particles. The chemical composition of free-iron particles was analyzed to be Fe 93.2 at. %, and Ti 2.9 at. %.

IV. CONCLUDING REMARKS

Ti-modified (α-Fe)-$Nd_2Fe_{14}B$ nanocrystalline two-phase alloys with soft iron particles embedded in hard $Nd_2Fe_{14}B$ matrix were prepared by melt spinning and annealing. The grain size of $Nd_2Fe_{14}B$ is 20–60 nm while that of the soft iron particles is 11–30 nm. The coercivity of the annealed flakes decreased dramatically with increasing particle size of the free iron, following the same tendency of a theoretical calculation by Schrefl *et al.* The 1 at. % Ti-containing flakes show the highest coercivity of 11.1 kOe. Its $(BH)_m$ value is about 16 MGOe despite the lower Nd and B content than stoichiometric $Nd_2Fe_{14}B$.

Magnetization processes in remanence enhanced materials (invited) (abstract)

R. Street, P. Allen, J. Ding, E. Feutrill, L. Folks, P. A. I. Smith, and R. C. Woodward
Research Centre for Advanced Mineral and Materials Processing, Nedlands 6009, Australia

Isotropic assemblies of hard and soft magnetic phases in nanocrystalline form have been produced by high energy ball milling and melt spinning. These materials exhibit remanence enhancement, i.e., the remanence exceeds $0.5M_{sat}$, the value expected of an isotropic material. The phenomenon has been investigated using models in which interaction energy across the interfaces between magnetically hard and soft components is taken into account. An example of such a two-dimensional model will be discussed. Measurements have been made of the magnetic properties of SmFeN, Sm(Fe,Co), and NdFeB two phase nanocrystalline materials. All of them exhibit remanence enhancement. The time dependent behavior of materials exhibiting remanence enhancement is unusual. Magnetic viscosity occurs on both branches of recoil loops as well as on the initial magnetizing and demagnetizing curves.

Polarized neutron reflectometry measurements were carried out on a thin-film Co-Re multilayer sample with Re thickness of 6 Å which is at the peak of the first oscillation of the magnetoresistance. Antiferromagnetic coupling between successive Co layers is observed at in-plane magnetic fields below 0.1 T. Towards the low field end of this regime, the axes of the antiferromagnetic domains are distributed relatively uniformly in the sample plane but at ~0.1 T the moments flop perpendicular to the applied field. As the field is increased further, the Co moments are pulled into the field direction producing a partial ferromagnetic alignment. At 0.5 T, the highest field where the measurements have been made, the antiferromagnetic to ferromagnetic transition was found to be only ~50% complete, indicating that the saturation field required for Co-Re system is much higher than that for Co-Cu multilayers of similar layer spacing.

I. INTRODUCTION

Multilayers composed of a ferromagnetic metal (Co, Fe, Ni)[1-5] separated by a nonmagnetic transition metal (such as Cu, Cr, Ru, and Ag) exhibit oscillatory interlayer magnetic coupling which has stimulated considerable fundamental and technological interest. In these materials, the coupling of adjacent magnetic layers oscillates between antiferromagnetic (AFM) and ferromagnetic (FM) alignment as a function of the nonmagnetic spacer thickness with a period about 10 Å for most systems.[3] This period can be understood in terms of the Ruderman–Kittell–Kasuya–Yosida interaction and the topological character of the Fermi surface of the nonmagnetic spacer layer.[6] Further, a strong negative magnetoresistance has been found in such multilayer films when the initial antiparallel magnetization alignment of adjacent layers is brought into parallel alignment by an external magnetic field.[1] As a result, the magnitude of the magnetoresistance oscillates with the nonmagnetic spacer thickness[2,3] and is attributed to spin-dependent scattering of the conduction electrons.[7]

We have recently demonstrated[8,9] that the magnetoresistivity of Co-Re multilayers also oscillates as a function of the Re layer thickness, with a small $\Delta R/R$ peak value of 1% and a large saturation field value near 1 T at low temperatures. Although the magnetoresistance is relatively small compared with other systems such as Co-Cu, the large fields required for the saturation of magnetoresistance are comparable with those in Co-Cu, indicating that the interlayer coupling is relatively strong for the Co-Re multilayers. In order to examine the interlayer magnetic coupling in detail, we have undertaken a series of polarized neutron reflectivity measurements on a sample with a Re layer thickness of 6 Å, chosen to be at the peak of the first oscillation of the magnetoresistance. Small angle spin-polarized neutron reflectometry is sensitive to both the nature of the interlayer coupling as well as the orientation of the internal magnetic axes with respect to the external applied magnetic field as has been shown for molecular-beam-epitaxy-grown (MBE) Co-Cu multilayers.[10]

II. EXPERIMENTAL DETAILS

The sample studied was taken from a series of samples[11] with layer structures substrate/Re(50 Å)/[Co(24 Å)/Re(t Å)]$_{\times 50}$/Re(10 Å) deposited on oxidized Si substrates using a modified single-source rf triode sputtering system. The additional 10 Å Re overlayer was included to inhibit oxidation of the Co layer immediately underneath. The deposition system was pumped to a base pressure $\sim 1\times10^{-7}$ Torr before sputter deposition at a pressure of 4.0 mTorr argon and a rf power of 88 W. With a substrate-target distance of 5.5 cm, typical deposition rates were 2.1 Å/s for Co and 2.0 Å/s for Re. The structural characterization of the samples was performed by low- and high-angle x-ray diffraction measurements.[9] Low-angle reflectivity data show three superlattice peaks, confirming a well-defined composition modulation along the growth direction. In addition, high-angle x-ray diffraction data indicate coherent and highly textured structures with an hcp [002] direction normal to the film plane. X-ray linewidths suggest an in-plane grain size of about 200–300 Å for this sample.

The neutron reflectivity measurements were carried out at the NRU reactor, Chalk River, with the C5 spectrometer of the DUALSPEC facility. The spectrometer was fitted with a

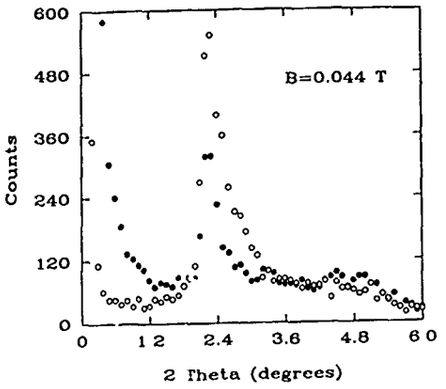

FIG. 1. Polarized neutron scattering intensity as a function of the scattering angle 2θ (2theta) at $B=0.044$ T. NSF scattering is plotted as filled circles and SF scattering as open circles.

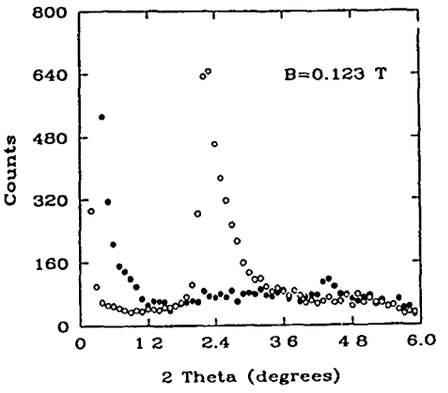

FIG. 2. Polarized neutron scattering intensity as a function of the scattering angle 2theta at $B=0.123$ T. NSF scattering is plotted as filled circles and SF scattering as open circles.

Cu_2MnAl Heusler alloy monochromator and analyzer, a pyrolytic graphite filter, and a Mezei-type spin flipper tuned for the selected neutron wavelength of 2.37 Å in the scattered beam. This setup allowed us to measure non-spin-flip (NSF) and spin-flip (SF) scattering of polarized neutrons by the sample. Since the Heusler alloy reflects only "spin down" neutrons the scattering processes correspond to $S(Q)_{down\text{-}down}$ and $S(Q)_{down\text{-}up}$. The sample was mounted in a cryostat with a horizontal magnetic field almost parallel to the multilayer planes. A small misalignment of the field of ~3° was required in order to avoid the neutron shadow caused by the liquid-helium feed tube for the lower part of the magnet. Specular reflectivity measurements were carried out at small glancing angles (<6°) with the scattering vector perpendicular to the multilayers. Sample temperatures were in the range from 4.2 to 250 K; only weak temperature dependences were observed and, in this paper, only low temperature data are presented.

III. RESULTS AND DISCUSSION

Magnetic neutron scattering is sensitive only to the components of the magnetic moment that are perpendicular to the scattering vector, i.e., that lie in the plane of the multilayer. Since the neutrons are polarized along the applied field B, the in-plane components of the moment parallel and perpendicular to B are observed as NSF and SF scattering, respectively.

Neutron reflectivity curves measured at three values of B are shown in Figs. 1–3. In general, resolved peaks are observed at three regions of scattering angle. The large peak at very small angles arises mostly from the unscattered neutrons. Additional small angle scattering is seen for the NSF channel due to finite critical angle for total external reflection. No total external reflection is seen for the SF channel. Additional peaks are found at $2\theta=4.5°$, arising from the structural period of 30 Å for this sample, and at $2\theta=2.3°$, corresponding to twice the structural period due to the AFM stacking of adjacent Co layers.

At the lowest applied field ($B=0.044$ T), specular peaks at $2\theta=2.3°$ are observed in both the NSF and SF scattering channels (Fig. 1), confirming that the interlayer magnetic order in the zero-field limit is AFM. The intensity ratio between the SF and NSF peaks in Fig. 1 is 2:1, indicating that in-plane AFM order is predominantly oriented perpendicular to B but approximately 30% of the moments remain parallel to B at this value of the field. For antiferromagnetically coupled layers in an applied field the magnetic energy is reduced if the moments are perpendicular rather than parallel to the field. The observation of AFM peaks in both scattering channels at $B=0.044$ T therefore indicates that there is a small amount of in-plane anisotropy present for the Co layers. A completely spin-flopped state of the sample, signaled by a purely SF scattering at the AFM peak position, is observed at 0.123 T (Fig. 2). Assuming the moment per unit area of each Co layer to be 3.5×10^{-4} G cm ($M\times t_{Co}\sim1446$ G×24 Å), we estimate the magnitude of the in-plane anisotropy to be ~0.4 erg/cm^2.

In Fig. 2 ($B=0.123$ T) the small NSF peak at $2\theta\sim4.5°$ is due to the establishment of a small net moment parallel to B. Note that the NSF signal in the corresponding range of Fig. 1 is undetectable above the background. More recent low-field measurements (to be published elsewhere)[12] show that there is indeed a very weak peak at this position of purely nuclear

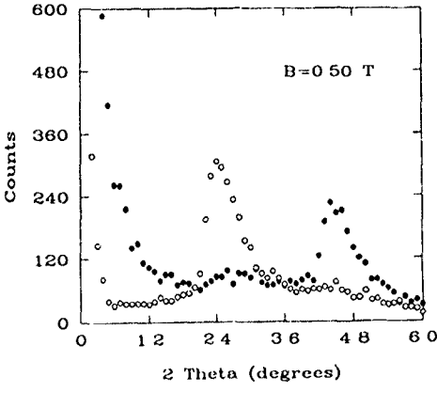

FIG. 3. Polarized neutron scattering intensity as a function of the scattering angle 2theta at $B=0.50$ T. NSF scattering is plotted as filled circles and SF scattering as open circles

origin [as confirmed by measurements of the two NSF cross sections, $S(Q)_{\text{up-up}}$ and $S(Q)_{\text{down-down}}$].

Measurements at fields ≥ 0.3 T reveal the development of a FM component at the expense of AFM order. At $B=$ 0.5 T the intensity of the FM peak is almost equal to that of AFM peak, indicating that the AFM to FM transition is halfway complete (Fig. 3). This result is consistent with the variation of transverse magnetoresistance in a similar sample with $t\sim 5$ Å, where $\Delta R/R$ is reduced to half of its zero-field value in an applied field of 0.5 T.[8]

IV. CONCLUSION

Antiparallel alignment of the Co layer moments at low fields, development of a spin-flop state at intermediate fields, and a gradual transition to parallel alignment at high fields indicate a classical AFM order with relatively strong interlayer coupling. Qualitatively similar behavior was found for MBE-grown Co-Cu multilayers[10] although significant FM order was also detected in AFM samples resulting from FM bridges due to pinholes in the films. Our sputtered Co-Re sample shows no low field FM order making it an ideal matrix for studying the spatial distribution of the magnetization in a system with antiferromagnetically coupled layers. Such an analysis is currently in progress.[12]

Interlayer exchange coupling versus ferromagnetic layer thickness in asymmetric Co/Ru/Co trilayer films

L. Zhou, Z. Zhang, and P. E. Wigen

A dependence of the interlayer exchange coupling coefficient A_{12} on the Co layer thickness has been observed in asymmetric Co(32 Å)/Ru(t_{Ru})/Co(t_2) trilayer structures for several series within which t_{Ru} is a constant. As a function of the second Co layer thickness, the amplitude of A_{12} varies significantly but the sign of A_{12} does not change within each series. In both parallel and antiparallel coupled structures, the variation length Δt_2 between the maximum and the minimum coupling strength is rather large (about 10 Å) and consistent from series to series.

I. INTRODUCTION

Since the discovery of antiparallel coupling between Fe films across a Cr interlayer,[1] many studies have been done to evaluate the interlayer exchange coupling strength in various magnetic multilayer systems using ferromagnetic resonance (FMR) and Brillouin light scattering (BLS).[2–5] For a trilayer structure consisting of two ferromagnetic layers separated by a nonmagnetic spacer, the bilinear exchange coupling energy per unit surface area is defined as

$$A_{12}\frac{\mathbf{M}_1\cdot\mathbf{M}_2}{\mathbf{M}_1\times\mathbf{M}_2}, \tag{1}$$

where A_{12} is the exchange coupling coefficient and $\mathbf{M}_1$ and $\mathbf{M}_2$ are magnetization vectors in the first and second magnetic layers, respectively. The sign of A_{12} is chosen so that it is positive for an antiparallel coupled system and negative for a parallel coupled system.

While most work is devoted to the oscillation behavior of the interlayer exchange coupling with increasing interlayer thickness, little effort has been related to the dependence of the coupling on the thickness of the ferromagnetic layers. Recently, Bloemen *et al.*[6] have studied the coupling behavior in a (001) Co/Cu/Co trilayer structure with different Co layer thickness, and concluded that the interlayer coupling oscillates as a function of the Co layer thickness with a period of 6–7 Å. Their results are consistent with the prediction by Barnas[7] and Bruno.[8] Both the theoretical calculation by Barnas and Bruno and the experimental evidence by Bloemen *et al.* are done in symmetric trilayer systems (i.e., in each sample, the first Co layer thickness t_1 is equal to the second Co layer thickness t_2). In this paper we report the first experimental evidence for interlayer exchange coupling oscillations as a function of the Co layer thickness in asymmetric Co(32 Å)/Ru(t_{Ru})/Co(t_2) trilayer systems. The purpose for these series is (i) to observe the optic mode by creating an asymmetric anisotropy environment and (ii) to systematically investigate the variation of the interlayer exchange coupling with the magnetic layer thickness.

The interlayer coupling strength as well as the effective anisotropy energy within each magnetic layer has been evaluated using in-plane magnetization measurements and angular dependence of FMR measurements. In the antiparallel coupled in-plane magnetization curves, two transition fields $H_{cri,1}=A_{12}/\mathbf{M}_s\times(1/t_2-1/t_1)$ and $H_{cri,2}=A_{12}/\mathbf{M}_s\times(1/t_2+1/t_1)$ exist which separate the antiparallel, canted, and saturation states. The two transition fields can be used to evaluate the coupling coefficient A_{12}. However, the in-plane hysteresis loop for a parallel coupled system is degenerate with that of a noncoupled system and therefore cannot be used to evaluate the coupling strength. In contrast to the in-plane magnetization measurements, FMR can provide information of the exchange coupling strength and effective anisotropy energy for both parallel and antiparallel coupled systems.

II. EXPERIMENT

The Co(32 Å)/Ru(t_{Ru})/Co(t_2) structures were prepared in ultrahigh vacuum by evaporation on freshly cleaved mica substrates. In each of the four series, the Ru layer thickness is a constant (t_{Ru}=10, 12, 16, and 24 Å, respectively) while t_2 varies from 8 to 32 Å. Structure analysis using reflection high-energy electron diffraction and transmission electron microscopy indicates that the layers are grown epitaxially on the buffer layers, with good crystalline features and sharp interfaces.

It has been found that the magnetization vectors of the two Co layers are strongly antiparallel coupled in series I (t_{Ru}=10 Å) and series II (t_{Ru}=12 Å), parallel coupled in series III (t_{Ru}=16 Å), and antiparallel coupled in series IV (t_{Ru}=24 Å). This is similar to the coupling behavior observed in symmetric structures.[9] Series I and II are in the first antiparallel coupled region and series IV is in the second antiparallel coupled region while series III is in the parallel coupled region with respect to the Ru thickness. In-plane magnetization measurements were performed using a superconducting quantum interference device and alternating gradient force magnetometry magnetometers at room temperature. FMR measurements at both X-band (9.2 GHz) and K-band (23 GHz) frequencies have been performed at room temperature. The external field was rotated from the orientation parallel to the film plane, $\theta_H=90°$, to the orientation perpendicular to the film plane, $\theta_H=0°$, in 10° steps.

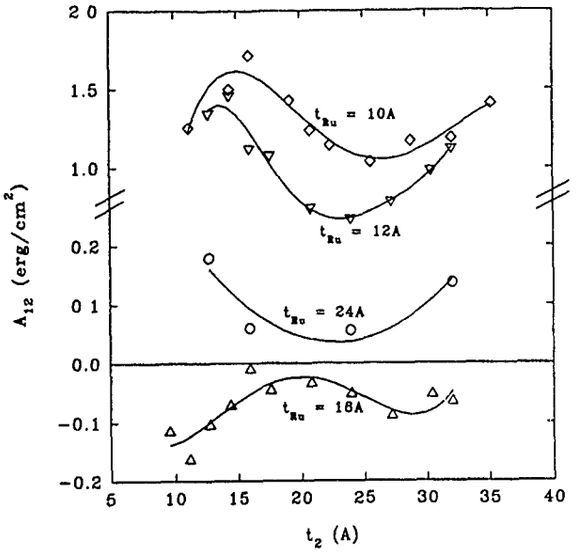

FIG. 2. The coupling coefficient A_{12} as a function of the second Co layer thickness, t_2, for four asymmetric series (I, II, III, and IV) having the structure of Co(32 Å)/Ru(t_{Ru})/Co(t_2) with t_{Ru}=10, 12, 16, and 24 Å, respectively. The curves indicated by ◇ and ▽ are calculated using in-plane magnetization measurements, and the curves indicated by ○ and △ are calculated using the FMR measurements. All results are at room temperature.

III. RESULTS AND DISCUSSIONS

All samples have an easy plane anisotropy energy when the second Co layer thickness $t_2 \geqslant 10$ Å. The saturation magnetization $\mathbf{M}_s$ per unit volume of Co is within 10% of the bulk Co value (1400 emu/cm^3) and is independent of the second Co layer thickness. No significant in-plane anisotropy field was found as expected for the hcp structure in the Co and Ru layers having the c axis normal to the film plane. Series I, II, and IV show typical antiparallel coupled magnetization curves, shown in Fig. 1. The in-plane saturation fields of ~16 kOe in these samples suggest that a very strong antiparallel coupling exists between the Co layers. Upon decreasing the second Co layer thickness t_2, the remanent magnetization increases and follows roughly the relation $\mathbf{M}_r/\mathbf{M}_s=(t_1-t_2)/(t_1+t_2)$ as expected. This shows the layer thickness is consistent from sample to sample. The well-defined shape of the hysteresis loops also indicates that the interlayer exchange coupling is quite uniform across the film plane. The coupling coefficient A_{12} in series I and II were calculated using the two transition fields $H_{cn,1}$ and $H_{cn,2}$ which can be obtained from the curves. In the parallel coupled system (series III), a nearly square hysteresis loop was obtained and the in-plane saturation field is less than 100 Oe for all of the samples in that series.

The FMR measurements of series I and II show only the acousticlike mode. But, both acoustic- and opticlike modes were observed in series III and IV. Therefore the angular dependence of resonance field was used to evaluate A_{12} for series III and IV. With increasing θ_H, one mode always stays on the low field side of the other mode. This is different from the behavior of a noncoupled trilayer structure unless the two layers have significantly different g values, which is not expected in these samples.

Figure 2 shows that the amplitude of A_{12} varies significantly as a function of the second Co layer thickness t_2, but the sign does not change within each series. In the antiparallel coupled systems (series I, II, IV), $|A_{12}|$ reaches maximum values (about 1.7, 1.5, and 0.18 ergs/cm^2 for series I, II, and IV, respectively) at $t_2 \sim 15$ Å, and minimum values (about 1.0, 0.6, and 0.06 ergs/cm^2 for series I, II, and IV, respectively) at $t_2 \sim 25$ Å. The variation amplitude, $|A_{12}^{max}|-|A_{12}^{min}|$, is on the same order as $|A_{12}|$ for each series which is larger than the theoretical predictions for the case of symmetric structure.[8] The variation length $\Delta t_2 \sim 10$ Å between maximum and minimum coupling strength is also much larger than the value obtained by Bloemen *et al.* in symmetric structures. In the parallel coupled system (series III), $|A_{12}|$ reaches extreme values at $t_2 \sim 20$ and 30 Å. $|A_{12}|$ is a minimum (about 0.01 ergs/cm^2) at $t_2 \sim 20$ Å, and a maximum (about 0.17 ergs/cm^2) occurs at $t_2 \sim 30$ Å.

From the FMR data the effective uniaxial anisotropy field $H_{u2,t}^{\text{eff}}$, which includes the demagnetization field $-4\pi\mathbf{M}_s$ and the perpendicular anisotropy field $2K_{u2,t}/\mathbf{M}_s$, was also evaluated for each Co layer. Figure 3 shows that $H_{u2,1}^{\text{eff}}$ for the 32 Å Co layer is a constant at −9.6 kG while $H_{u2,2}^{\text{eff}}$ for the second Co layer increases with decreasing t_2. The variation of $H_{u2,2}^{\text{eff}}$ can be expressed as using a bulk contribution $H_{\text{bulk}}^{\text{eff}}$ and a surface contribution H_s from each Co/Ru interface

$$t_2 \times H_{u2,2}^{\text{eff}} = t_2 \times H_{\text{bulk}}^{\text{eff}} + 2H_s, \tag{2}$$

where $H_{\text{bulk}}^{\text{eff}}$ is about −12.2 kG in these samples which agrees with the estimation using the demagnetization field (−17.6 kG) and the uniaxial anisotropy field (5.9 kG) of bulk Co. The surface anisotropy field H_s is quite large in these samples and corresponds to a surface anisotropy energy of $K_s \sim 0.40$ ergs/cm^2. A negative $H_{u2,2}^{\text{eff}}$ was obtained when t_2 is less than 10 Å, suggesting that the easy axis in the

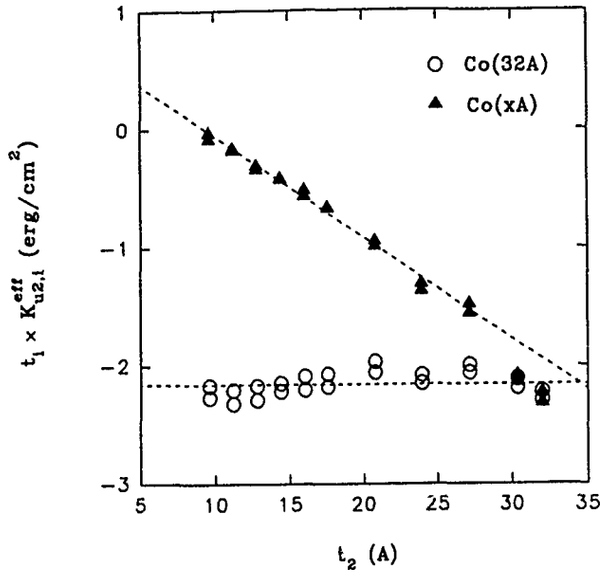

FIG. 3. The evaluation of $t_i \times K_{u2,i}^{eff}$ obtained from the FMR at 9.2 and 23 GHz as a function of the second Co layer thickness t_2 for the Co(32 Å)/Ru(16 Å)/Co(t_2) series at room temperature. The broken lines are the best fit using the expression described in the text.

second Co layer is in the normal film plane as expected from the in-plane and normal plane magnetization measurements in very thin films.

IV. CONCLUSION

The variation of the interlayer exchange coupling with the Co layer thickness in the asymmetric Co/Ru/Co trilayer structures has been investigated using the in-plane magnetization and angular dependence of FMR measurements. The results show that the coupling strength depends on the magnetic layer thickness. There is a significant variation of A_{12} on increasing the second Co layer thickness in both parallel and antiparallel coupled systems. This might be due to the different Fabry–Perot-like interference of electron Bloch waves within the individual magnetic layers. No change of the sign of A_{12} was observed in any of the series. The variation period between the maximum and minimum values of A_{12} is about 10 Å which is larger than the predicated value π/k_F from the free electron model, suggesting that the discreteness of the magnetic layer thickness and the moment distribution may have to be taken into account.[10]

A dependence of the strength of the antiferromagnetic coupling across Cu on the *Co layer thickness* has been observed. The Co thickness dependence displays two clear peaks consistent with the recently predicted oscillation period of 6.2 Å Co. Apart from the two peaks also several small peaks are visible on a scale of about 1 monolayer Co. Free-electron calculations indicate that these rapid variations in strength may result from slight differences between the slopes and starting points of the two Co wedges that were involved in the experiment.

Recent theoretical work by Bruno[1] and Barnaś[2] has shown that the interlayer exchange coupling between two ferromagnetic (FM) layers across a nonmagnetic (NM) metallic spacer layer may oscillate not only with the thickness of this spacer but also with the thickness of the ferromagnetic layers.

Systematic experimental studies investigating the detailed effect of the FM thickness upon the interlayer coupling are very scarce. Qiu *et al.*[3] and Chen *et al.*[4] studied the Co/Cu/Co (100) system for several Co thicknesses. However, their results were insufficient to reveal an oscillatory behavior. First experimental evidence for an oscillatory behavior as a function of the magnetic layer thickness was obtained by the present groups for a (001) Co/Ni/Co/Cu/Co/Ni/Co sandwich[5] and by Okuno and Inomata for Fe/Cr (100) multilayers.[6] In this article we summarize our experimental results[5] and discuss them using calculations based on the Bruno model.[1] Within the free-electron approximation, this model could be extended to include our experimental situation viz. a situation of, in principle, unequal FM layers which, in addition consist of multiple different FM layers (three in our case, Co/Ni/Co). To interpret or predict the behavior of these at first sight more complicated systems it is useful to recall the mechanism from which an oscillation with a FM layer thickness originates.

Bruno shows that the coupling problem can be described in terms of the reflection of electron waves at the potential steps at the various interfaces in the FM/NM/FM sandwich.[7] Here, the nonzero exchange spitting of the conduction bands in the FM layers is responsible for a difference in potential step heights for spin-up and spin-down electrons. This causes the reflection amplitude to be *spin dependent* resulting in a magnetic coupling. The coupling strength is larger for larger differences between the reflection amplitudes for spin-up and spin-down electrons. An oscillatory dependence of the coupling strength on the thickness of the FM layers is then, as Bruno argues, simply a result of multiple reflections of electron waves within the FM layers.[1] As in the case of light waves incident on a (multi)layer, the effective reflection amplitude of a layer (in our case a FM layer) is a result of the constructive and destructive interferences of the forward (transmitted) and backwards (reflected) traveling waves and depends upon the interplay between the layer thickness, the wavelength of the incident wave, and the wavelength within the reflecting medium. The latter is determined by the electronic structure of the FM layers and follows, in the large thickness limit, from the relevant extremal Fermi surface (FS) spanning vectors of the FM layer. From this "electron-optics" picture it is thus clear that if a FM layer is composed of, for example, a multilayer made of several different FM layers, the effective reflection amplitude of such a multilayer (and thus the coupling) will oscillate with the thickness of any of the constituent FM layers. This is exactly the case for our experimental system.

We have studied a molecular-beam-epitaxy-grown (001) Co/Ni/Co/Cu/Co/Ni/Co sandwich in which the two Co layers adjacent to the Cu spacer as well as the Cu spacer itself were deposited in the form of wedges oriented perpendicularly with respect to each other. This allowed for independent investigation of the Cu and Co layer thickness dependence of the coupling across Cu(001) in a single sample. In this way experimental artifacts are avoided that are related to changes in (i) deposition conditions, (ii) substrate quality, and (iii) layer thickness—changes that otherwise would have occurred in a series of separate samples. Especially slight changes in a presumably fixed Cu spacer layer thickness in an experiment of varying magnetic layer thickness would cause problems in our case since the coupling strength is extremely sensitive to the precise Cu thickness because of the presence of a short period oscillation with a period of about 2.6 ML Cu. Note that the latter problem was not encountered in the study of the sputtered Fe/Cr (100) samples of Okuno and Inomata[6] since only the long Cr period was present in their samples.

Two samples (referred hereafter as samples I and II) have been investigated. The typical composition of the magnetic layers in the samples was as follows: 30 Å Co/15 Å Ni/Co wedge (2.3 Å/mm). Further compositional details and information regarding the structure of the layers as obtained from low energy electron diffraction experiments can be found in Ref. 5.

The antiferromagnetic (AF) coupling behavior was in-

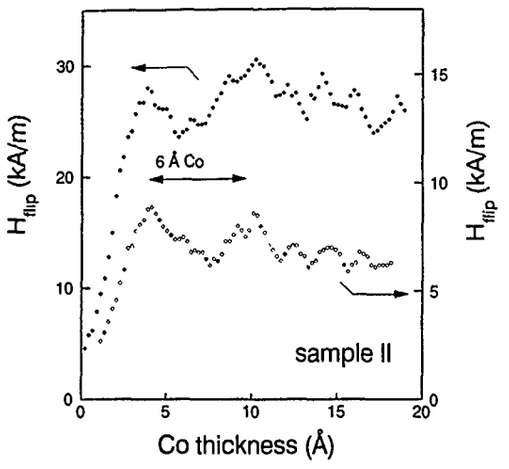

FIG. 1. The strength of the interlayer exchange coupling in the first and second AF peak as a function of the Co thickness for sample II.

vestigated by measuring hysteresis loops via the longitudinal magneto-optical Kerr effect. The behavior as a function of the Cu thickness displays a superposition of a long and a short period oscillation,[5] in accordance with earlier observations.[8,9] The presence of the short period in both samples indicates that these samples are of high structural quality. The dependence on the Co thickness of the strength of the first two AF maxima (at ≈9 Å Cu and ≈19 Å Cu) for sample II is shown in Fig. 1. An oscillatorylike behavior with an apparent period of 6–7 Å is observed in all experimental scans. From the electron-optics picture of Bruno it is immediately clear that this value is a property solely of Co. With varying Co thickness the effective reflection amplitude of the Co/Ni/Co FM layer (and thus the coupling) is modified in an oscillatory fashion with a period determined by the relevant wavelength in the Co layer. According to Bruno the latter is determined by the extremal spanning vector along the Γ-X line [(100) growth] in the spin-down FS of fcc Co. This vector yields a period of 3.5 ML or 6.2 Å Co which is in very good agreement with the present experiment. However, the functional shape of the experimentally obtained variation with Co thickness does not resemble a fully regular oscillatory behavior. Considering for example the behavior of the second AF peak, the lower curve in Fig. 1, two clear peaks are visible whereas around the position where the third peak is expected three smaller peaks occur with a spacing of about 2 Å. This behavior seems in contradiction with theory. In particular from the aliasing effect one would expect that because of the sampling at discrete Co planes, periodic variations in coupling strength should only occur on a scale larger than 2 ML (3.6 Å). This is true in the ideal situation. However, in the present experiment *two* Co wedges are involved which may not be identical but may differ slightly in, e.g., their slope. In this respect we remark that with scanning Auge. electron spectroscopy (AES) the slopes were determined to be equal within 10% accuracy. In order to evaluate the effect of unequal Co wedges on the experimentally observed behavior and in particular if it is possible to explain variations in coupling strength on a scale of 1 ML Co, we have extended the model of Bruno[1] to our experimental geometry and performed a number of simulations. Before proceeding with the results we briefly describe the steps that we have undertaken to adapt the model to our situation.

First, to account for unequal wedges Eq. (4) in Ref. 1 is generalized to the case of unequal FM layers. As is clear from Ref. 1 this can be performed by a Taylor expansion of the first Eq. in Ref. 1. In principle this step is sufficient to evaluate if rapid variations in coupling strength may arise from unequal wedges. Second, to account for the effect of the two additional FM layers which are coupled to the Co wedge the model is extended to the case that each FM layer is composed of an arbitrary number of layers, i.e., to describe the system $FM_1^a/FM_2^a/\cdots/FM_k^a$/spacer/$FM_1^b/FM_2^b/\cdots/FM_l^b$ with k and l integers denoting the number of FM layers of which FM layers a and b are composed, respectively. To our knowledge the latter step can only be made easily within the free-electron approximation. Within this approximation it is straightforward to calculate the effective reflection amplitude of each FM multilayer. Continuity of the wave functions (plane waves) and their derivative at the interfaces directly enables one to write down a recursion relation for the reflection amplitude of an arbitrary multilayer. Using this relation instead of the Fabry–Pérot formula given by Bruno [Eq. (5) in Ref. 1] allowed us to calculate the Co thickness dependence of the coupling for the situation in which the slopes of the Co wedges differ and their starting point do not coincide.

The results of several calculations for 19.86 Å Cu, i.e., for the strength of the second AF peak, are shown in Figs. 2(a)–2(c). The calculated coupling strengths are normalized to the limit of infinite Co wedge thickness. In Fig. 2(a) the behavior is shown for the ideal case of two identical Co wedges. Here the aliasing effect is demonstrated for the Co dependence. The fundamental period $\lambda=\pi/k_f^{\downarrow}=2.49$ Å pertaining to the Fermi wave vector $k_f^{\downarrow}$ of the spin-down fcc Co FS, yields after aliasing (with 1.805 Å Co ML thickness) a period of 6.1 Å. In Fig. 2(b) the ideal case is again calculated. However, for this calculation the situation that a Co layer consists of a nonintegral number of monolayers (incomplete coverage) is also calculated. This is done from a linear combination of the coupling across two independently patchy interfaces. Incomplete coverage is thus treated as follows: We define $J(n,m)$ as the coupling strength for the combination of n integral number of Co monolayers in Co wedge A and m monolayers in Co wedge B. The coupling $J'(t_A,t_B)$ for the situation that the thicknesses t_A and t_B at Co wedge A and B, respectively, are a nonintegral number of monolayers is calculated from

$$J'(t_A,t_B)=J(n,m)(1-f_A)(1-f_B)+J(n,m+1)\times(1-f_A)f_B+J(n+1,m)\times f_A(1-f_B)+J(n+1,m+1)f_Af_B.$$

Here, $f_{A(B)}$ represent the fractional coverages defined by $t_A=n+f_A$ and $t_B=m+f_B$ with $0\leq f_{A(B)}\leq 1$. Considering Fig. 2(b) it is clear that even for the ideal case of equal wedges, fractional coverages result in additional peaks like the small one between the third and fourth monolayer (±6 Å). Such features are a direct result of the asymmetric Co layer thick-

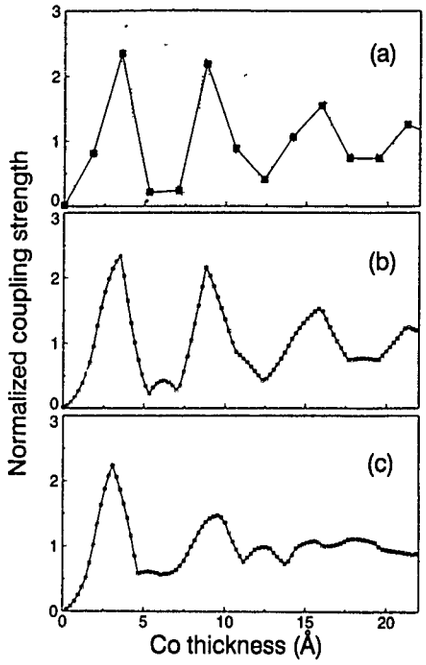

FIG. 2. Free-electron calculations of the Co thickness dependence of the coupling strength for 30 Å Co/15 Å Ni/Co/19.86 Å Cu/Co/15 Å Ni/30 Å Co. The values are normalized to the strength of infinite Co thickness limit. Calculation parameters are k_f^{Cu}=1.471 Å^{-1},$k_f^{\downarrow Co}$=1.261 Å^{-1}, $k_f^{\uparrow Co}$=1.363 Å^{-1}, $k_f^{\downarrow Ni}$=1.362 Å^{-1}, $k_f^{\uparrow Ni}$=1.389 Å^{-1} (Ref. 10).

ness combinations [$(n,n+1)$ and $(n+1,n)$]. It thus appears that for the present case in which two active layers are involved one is not allowed to make a linear interpolation [such as in Fig. 2(a)] between the situation in which both Co layers are n ML thick (n,n) and the situation in which both Co layers are $n+1$ ML thick [$(n+1,n+1)$]. The experimentally observed rapid variations in coupling strength may originate from this phenomenon. In an attempt to fit a free-electron calculation to the experimental strength dependence of the second AF peak (Fig. 1) we have tried a number of combinations for the wedge slopes and starting points of the Co wedges. Figure 2(c) shows a calculation in which the Co wedge slopes differed by about 10% from the AES determined value of 2.3 Å/mm viz. 2.5 Å/mm for Co wedge A and 2.1 Å/mm for Co wedge B. In addition wedge A has been given an offset of 0.5 Å with respect to wedge B. From the combinations we have tried it appeared that the first two peaks are relatively insensitive to modifications of the wedge parameters so that their separation remains a good measure for the oscillation period. The behavior at the larger Co thicknesses appears more susceptible. From Fig. 2(c) it is clear that the third and fourth peak may even disappear. Instead three smaller peaks appear with a spacing which is considerably smaller than the 6.2 Å oscillation period. The qualitative agreement with the experiment is striking, suggesting that the originally proposed interference/beating ef-

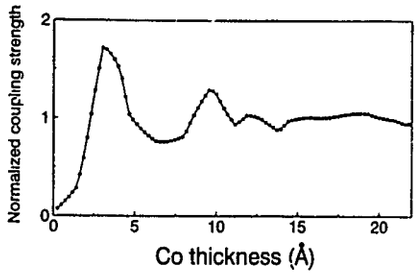

FIG. 3. Free-electron calculation of the Co thickness dependence of the coupling strength for the first AF peak, i.e., for 30 Å Co/15 Å Ni/Co/7.22 Å Cu/Co/15 Å Ni/30 Å Co. The values are normalized to the strength of infinite Co thickness limit.

fects in Ref. 5 may not be necessary to explain the behavior at the larger Co thicknesses. We did not attempt to obtain a better fit by varying more parameters, e.g., by introducing a difference in the thicknesses of the two Ni layers which were adjacent to the Co wedges. One should realize that the present model, although it explains many of the observed features, is a free-electron approximation and therefore seems inappropriate to make a comparison with the experiment on a detailed level. This is also reflected by the calculation shown in Fig. 3 representing the behavior for the *first* AF peak (calculation at 7.22 Å Cu). Here, the same Co wedge parameters were used as those to obtain the reasonable fit for the second AF peak [Fig. 2(c)]. The simulation does not display the smaller sharp features at the higher Co thicknesses such as observed in the experiment [the upper curve in Fig. 1]. Instead the variations are more gradual. What does agree are again the important features. Apart from the ones we already mentioned it is seen that the relative oscillation amplitude for the first AF peak is *smaller* than that for the second AF peak, (compare Figs. 3 and 2(c)). This is in agreement with the experiment where the peaks as afunction of the Co thickness are more pronounced for the second AF peak than for the first AF peak (Fig. 1).

The authors wish to express their gratitude to P. Bruno for explaining the application of the complex-path integration technique.

Cumulative interface roughness and its influence on the magnetization process in antiferromagnetically coupled $(Ni_{80}Co_{20}/Cu)\times N$ multilayers is studied. In these multilayers, Cu and $Ni_{80}Co_{20}$ thicknesses are fixed at 20 and 15 Å, respectively, in order to obtain the antiferromagnetic coupling at the second oscillation peak of giant magnetoresistance (GMR) versus Cu thickness. Low-angle x-ray reflectivity measurements show that cumulative interface roughness increases with increasing bilayer number N. In-plane magnetization hysteresis measured with both SQUID and surface magneto-optic Kerr effect (SMOKE) magnetometers are compared. When the cumulative interface roughness is significant, SMOKE hysteresis loops, which are sensitive to the top 5 or 6 magnetic layers, display a nonlinear plateau region at small fields. Comparison of low-angle x-ray, and SMOKE results show that interfaces of relatively high quality in top layers only exist for sputtered multilayer with $N<10$.

INTRODUCTION

Reports of antiferromagnetic (AF) interlayer coupling and the associated giant magnetoresistance (GMR) in Cu-spaced ferromagnetic multilayers, such as Co/Cu,[1,2] NiFe/Cu,[3] NiFeCo/Cu,[4] and NiCo/Cu,[5,6] have stimulated great interest in these materials. Within each magnetic layer, demagnetizing fields due to the layer's shape anisotropy stabilize the in-plane easy axes. The AF coupling of neighboring magnetic layers results in net zero magnetization in the multilayers at zero field.[6] The application of in-plane fields align the magnetic moments through in-plane rotation. Below saturation in the absence of any in-plane anisotropy there is a linear relation between the magnetization M and the applied magnetic field H:[7]

$$M=\frac{M_s^2 t_M}{4J}H. \tag{1}$$

Where J is the AF coupling constant between two neighboring magnetic layers, t_M and M_s are, respectively, the thickness and saturation magnetization of each magnetic layer. Therefore, J can be obtained from magnetization hysteresis loops.

Theoretical analysis based on the RKKY model predicts that the AF coupling is weakened by the introduction of interface roughness,[8] whereas experiments explicitly show that interface roughness introduced by changing the sputtering parameters can enhance the GMR effect.[9] In this paper, we report specifically on the effects of cumulative interface roughness on the magnetic properties of AF-coupled multilayers. The cumulative interface roughness is the accumulation of small intrinsic interface roughness in each layer;[10] its effects become more pronounced when the number of bilayers increases. Magnetization measurements from a SQUID magnetometer, which measures the effects of the overall interface roughness, are compared to surface magneto-optic Kerr effect (SMOKE) measurements, which are sensitive only to the top few layers where the cumulative interface roughness reaches its maximum value. SMOKE measurements for multilayers with a different bilayer number can, therefore, show direct information on the effects of cumulative interface roughness on the magnetization process in AF-coupled multilayers.

EXPERIMENTAL RESULTS AND DISCUSSION

Previous experiments[5,6] have shown that $Ni_{80}Co_{20}$/Cu multilayers exhibit an oscillatory GMR as a function of Cu spacer thickness and a well-defined simple AF ordering for Cu spacer thickness at 20 Å. In the present work $(Ni_{80}Co_{20}15$ Å$/Cu_{20}$ Å$)\times N$ multilayers with 50-Å $Ni_{80}Co_{20}$ buffer layer were deposited on Si wafers, by dc magnetron sputtering at room temperature. The base pressure before deposition was 2×10^{-7} Torr. With a sputtering pressure of 8.0 mT of argon, the deposition rates determined from the measured thickness of single films by low-angle x-ray reflectivity measurements were 1.5 Å/s for $Ni_{80}Co_{20}$ and 1.6 Å/s for Cu. A series of samples with N varying from 8 to 100 were prepared. Low-angle x-ray reflectivity measurements were performed for layer and interface characterizations and for estimating the cumulative interface roughness as a function of the bilayer number N. The room-temperature in-plane magnetization of the samples was measured using a SQUID magnetometer. The magnetization of the top few layers was studied using SMOKE magnetometer.

Figure 1 shows low-angle x-ray reflectivity results for the typical samples with different bilayer number N. All samples exhibit clear first-order superlattice Bragg peaks although the electronic contrast between the two constituent layers is very small. With increasing N, the second-order superlattice Bragg peaks are gradually damped, suggesting an increase of interface roughness.[11] Clear thickness oscillations (or lattice fringes) between superlattice Bragg peaks are observed for samples with $N<15$. For a finite thickness (<1000 Å) of the film, suppressing of the lattice fringes with increasing N is also partially correlated to the increased outer surface roughness.[12] The low-angle x-ray reflectivity has been analyzed using an optical model.[12] From the fit to the

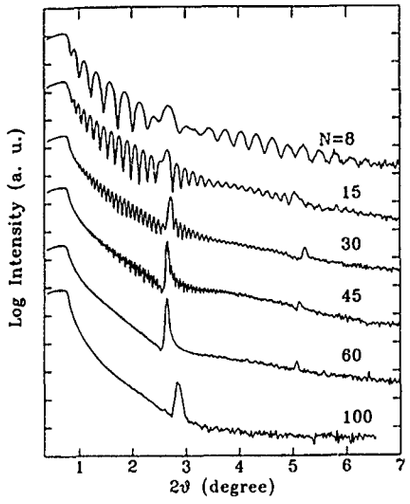

FIG. 1. Low-angle θ-2θ x-ray diffraction spectra of a selected series of ($Ni_{80}Co_{20}$ 15 Å/Cu 20 Å)×N multilayers. For clarity, the curves have been displaced vertically.

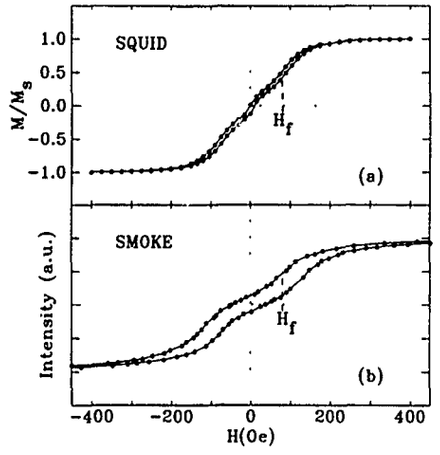

FIG 3. Magnetization of a typical ($Ni_{80}Co_{20}$ 15 Å/Cu 20 Å)×45 sample measured by (a) SQUID (normalized to M_s), and (b) SMOKE (arbitrary unit). It is indicated that the nonlinearity of the magnetization curve can be observed near a critical field H_f.

data the interface roughness and the outer surface roughness can be derived. Figure 2 shows that the outer surface roughness σ_s increases monotonically with increasing N. Intensities of second-order superlattice peaks, which decrease with increasing N, is also shown in Fig. 2.

Figure 3(a) shows the overall in-plane magnetization measured with a SQUID magnetometer for a ($Ni_{80}Co_{20}$15 Å/Cu_{20} Å)×45 multilayer having moderate cumulative interface roughness. Slight deviation from linear magnetization is observed near a critical field H_f. Figure 3(b) shows the magnetization of the top few layers measured using SMOKE. The deviation from a linear curve is more pronounced than it is for the SQUID curve which represents the average magnetization of the whole multilayer. Since SMOKE measurements were made using the 6328-Å He-Ne laser which has a penetration depth of approximately 200 Å, the SMOKE hysteresis loop typically represents the magnetic property of the top 5 or 6 bilayers of multilayer.

For samples with $N=8$ both SQUID and SMOKE measurements show linear $M-H$ relations below saturation fields. The saturation moment M_s of the 15-Å $Ni_{80}Co_{20}$ layer is about 620 emu/cm^3, which yields a value of $J\sim5.8\times10^{-3}$ erg/cm^2 for the second AF coupling peak in $Ni_{80}Co_{20}$/Cu multilayers.[6] This value is much smaller than the strength of the second AF coupling peaks found in other Cu-based multilayer systems,[2-4] indicating a very weak AF coupling between adjacent $Ni_{80}Co_{20}$ magnetic layers across 20-Å-thick Cu spacer layers. The M_s values measured with the SQUID magnetometer do not depend on N. This implies that the intermixing at the interfaces is not changing significantly with increased cumulative interface roughness.

Figure 4 shows SMOKE measurements for different bi

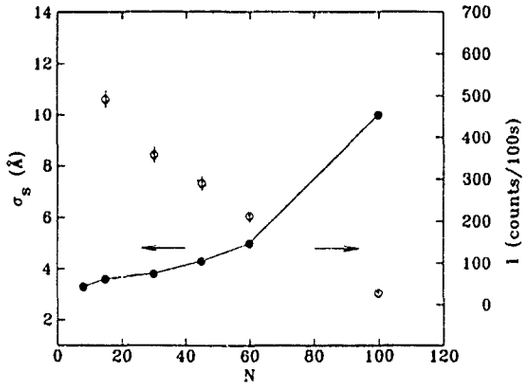

FIG 2. Dependence of σ_s and I on N Here σ_s is the outersurface roughness, and I the intensity of second-order superlattice Bragg peaks.

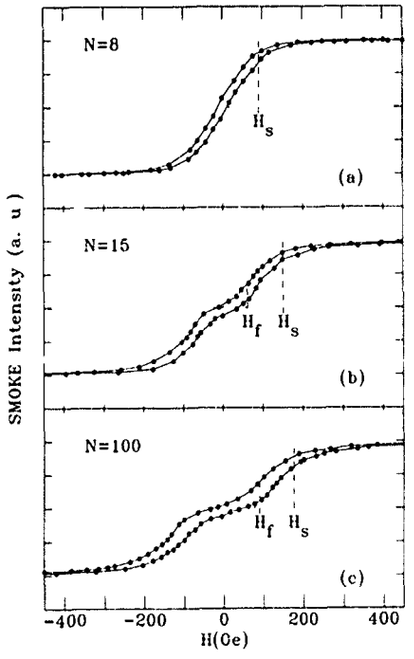

FIG. 4. SMOKE magnetization measurements of samples with different bilayer numbers. (a) $N=8$, (b) $N=15$, and (c) $N=100$ Two critical fields, i.e., saturation fields H_s and flip fields H_f, are indicated in the figures.

layer numbers. Figure 4(a) shows that the magnetization relation is nearly linear below saturation fields for the sample with $N=8$ where the interfaces are presumably flat. Figure 4(b) shows the result for the sample with $N=15$, where a plateau region with a relatively small slope is observed at low fields, and failure of the linear $M-H$ relation is clearly seen. As the bilayer number N increases up to 100, the cumulative interface roughness is considerably large, and the plateau region becomes more striking as indicated in Fig. 4(c). From low-angle x-ray reflectivity analyses and SMOKE measurements, we conclude that the nonlinear $M-H$ behavior in samples with large N are related to cumulative interface roughness which becomes significant as the bilayer stacking increases.

In some layered structures with nonideal interfaces, terraced interface roughness results in an extrinsic biquadratic coupling between ferromagnetic layers in the presence of intrinsic bilinear coupling.[13] Although the nonlinearity of the $M-H$ curve observed in $Ni_{80}Co_{20}$/Cu multilayers could, in principle, be explained by an additional biquadratic coupling term, a preliminary calculation indicates that the coefficient of this term is positive. However, previous studies have shown the sign of the biquadratic coupling to be negative.[13–15] In a multilayer with cumulative interface roughness, the profile correlation among consecutive interfaces increases toward the top of multilayer,[10] which distinguishes this type of roughness from other structural imperfections (e.g., the layer's terraced thickness fluctuation, etc.). We consider that such a cumulative roughness may produce a local magnetic anisotropy that is likely to be related to the interface and surface strains. Qualitatively, the two critical points (i.e., H_f and H_s) identified in an $M-H$ loop for a rougher sample, as illustrated in Fig. 4(c), should correspond to the strong- and weak-coupling limits of the exchange with respect to the anisotropy.[16] Modeling such an extrinsic roughness-related anisotropy is undertaken in order to interpret quantitatively the unusual magnetization behavior.

CONCLUSIONS

We have studied the cumulative interface roughness and its effect on magnetization in AF-coupled multilayers $(Ni_{80}Co_{20}15\ Å/Cu15\ Å)\times N$ using x-ray reflectivity and SMOKE. Both experiments show that interface roughness increases with an increasing number of bilayer period. SMOKE measurements are sensitive to the roughest region of the sample, namely the top several layers. Relatively flat interfaces only exist in sputtered multilayers with bilayer number $N<10$ for which SMOKE magnetization curves are linear below saturation fields as predicted from Eq. (1). As superlattice periods increase, deviation from linearity in $M-H$ curves gradually becomes large, which can be attributed to a roughness-related extrinsic anisotropy.

The elaboration of four different sample types, namely, isolated NiFe or Co layers in their Cu environment and full, exchange decoupled, [Cu/NiFe/Cu/Co/Cu] periods with either the Co or NiFe layers in the vicinity of the free surface has allowed for a detailed study of the magnetization process of the constitutive layers of one period of a "hard–soft"-type spin valve. The domain distribution and magnetization fluctuations within domains have been monitored by Kerr microscopy. The experiments point to a strong influence of dipolar coupling on the properties of the soft permalloy layer, with a dramatic increase of the NiFe film coercive field with respect to the corresponding quantity in an isolated NiFe layer. The macromagnetization fluctuations detected in the NiFe layer appear most likely linked to fluctuations of low amplitude occurring in the Co layer in the vicinity of the NiFe coercive field.

I. INTRODUCTION

A recent study[1] of magnetization reversal in ferromagnetically exchange coupled [$Ni_{80}Fe_{20}$/Cu/Co] sputtered multilayers revealed the existence of strong magnetization fluctuations in the soft layers of those artificial stacks consisting of piled-up hard and soft magnetic layers separated by a nonmagnetic spacer. Fluctuations were ascribed to the existence of a random distribution of the cubic anisotropy axes in the polycrystalline Co layers.[2] On the other hand, previous experiments in exchange uncoupled, hard–soft-type, three-layer [PtCo/SiO_2/NiFe] structures[3] pointed to the influence of dipolar interactions on the magnetic properties of the soft layer. Moreover, a field dependent magnetostatic coupling was also found to operate between the two soft layers of a [NiFeCo/Au/NiFe] sandwich film and mediated by the rippling of magnetization.[4]

Since a significant increase of the Permalloy coercivity seems to be a common observation in the [$Ni_{80}Fe_{20}$/Cu/Co] system,[5,6] a property detrimental to the use of such systems as low field, high magnetoresistance sensors, the ultimate aim of this study is to weigh the respective influences of exchange and dipolar couplings on this phenomenon. The present work, however, is limited to an analysis of the magnetization process and coercivity under conditions of a sole magnetostatic coupling.

II. EXPERIMENT

Experiments carried out for this work include VSM magnetometry and Kerr optical microscopy. Two different types of samples have been studied. Samples of the first species are made of sputtered [50 Å Cu/M/30 Å Cu] layers grown over a 50 Å Cr buffer deposited on (100) Si substrates, where M is either a 100-Å thick $Ni_{80}Fe_{20}$ or a 50-Å Co layer. Such samples are useful to separately investigate the magnetic domain structures of a single layer, whether hard (Co) or soft (NiFe). In these reference samples, the environment of each isolated magnetic layer is identical to that found in the more complex stacks described hereafter. The two other samples are composed by one period of a spin valve, respectively [Si(100)/50 Å Cr/50 Å Cu/100 Å $Ni_{80}Fe_{20}$/100 Å Cu/50 Å Co/30 Å Cu] and the symmetrical stacking, i.e., [Si (100/50 Å Cr/50 Å Cu/50 Å Co/100 Å Cu/100 Å $Ni_{80}Fe_{20}$/30 Å Cu]. In these artificial structures, the Cu spacer thickness has been chosen to be sufficiently large in order to solely retain a dipolar coupling between the magnetic layers. Besides, since no magnetic field was applied during the sputtering process, virtually anisotropy-free samples were obtained.

For each sample, following the application of a saturation field along a selected in-plane direction, a domain pattern is first nucleated under reverse field **H**, the magnitude of which is stack dependent. The pattern is then observed under two different illumination conditions. For instance, in the figures labeled (a), the trace of the plane of incidence for the probing light is parallel to the saturation field. A first difference image (pattern minus saturated state) provides a picture of the domain distribution with a magnetization either parallel or antiparallel to **H**. A 90° rotation of the sample or of the plane of incidence followed by a second difference image (saturated state minus pattern) reveals, since the plane of incidence is now perpendicular to the average magnetization direction in each domain, the magnetization fluctuations within domains [figures labeled (b)].

In samples incorporating a single NiFe magnetic layer, magnetization reversal occurs through the nucleation of large lateral size domains, typically a few hundred microns wide. For instance, two domains with opposite magnetizations are shown in Fig. 1(a) ($H \approx -2$ Oe). The nonuniformity of the contrast in the domain with magnetization parallel to the saturated state (the white domain) already points to the existence of magnetization fluctuations within domains, a fact confirmed by the observations in Fig. 1(b). Due to the weak contrast observed in Fig. 1(b), the existence of only small amplitude fluctuations is inferred. The coercive field amounts to ≈ 1.5 Oe [Fig. 1(c)] whereas the tilted shape of the hysteresis loop may be ascribed to the existence of a range of nucleation fields within a sample with a fairly macroscopic lateral size (cm range) and/or correlated to the ripening of magnetization fluctuations.

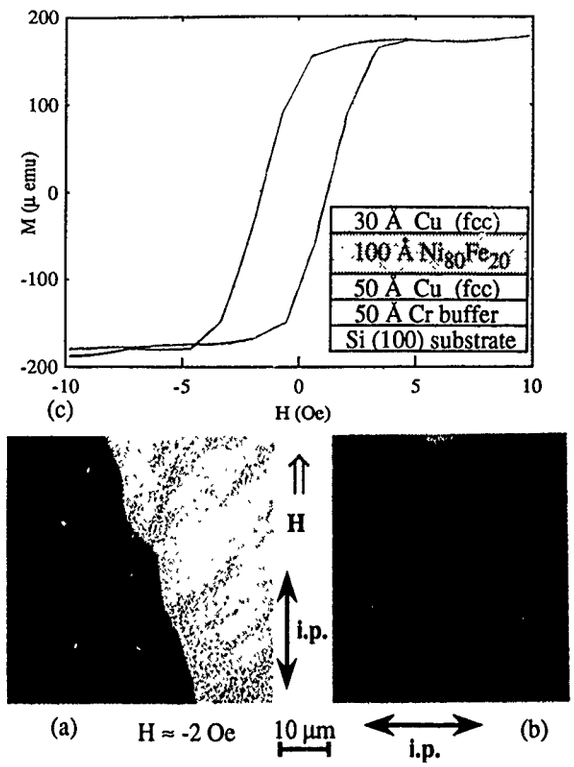

FIG. 1. Two similar domain structures generated under reverse **H** field ($H \approx -2$ Oe), observed in a single NiFe magnetic film bounded by two Cu layers. (a) Plane of incidence i.p.$\|$**H**; (b) i.p.$\perp$**H**; (c) is the corresponding hysteresis loop.

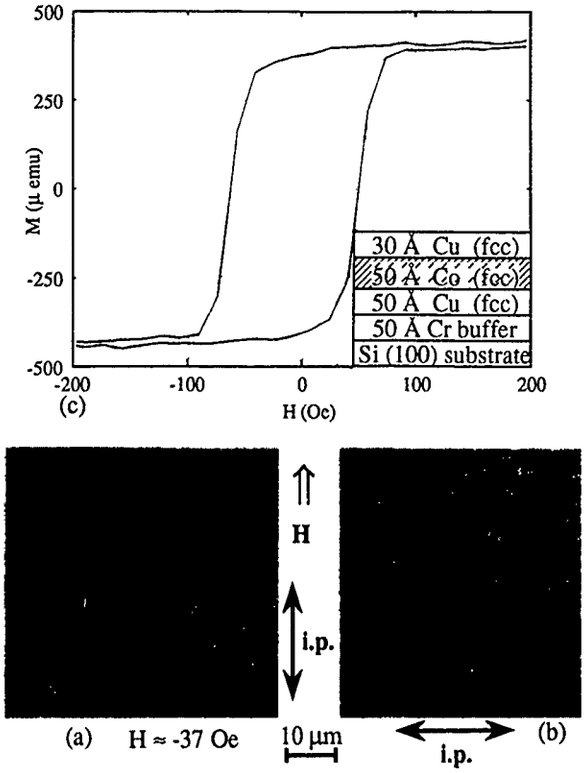

FIG. 2. Two similar domain structures generated under reverse **H** field ($H \approx -37$ Oe), observed in a single Co magnetic film bounded by two Cu layers. (a) Plane of incidence i.p.$\|$**H**; (b) i.p.$\perp$**H**; (c) is the corresponding hysteresis loop.

A much more irregular pattern is observed under reverse field in samples consisting of a single (fcc) Co magnetic layer [Fig. 2(a)]. Figure 2(b) exhibits the intensity modulations inside a domain of nonreverse magnetization [light grey shade domains in Fig. 2(a)], as recorded at the onset of magnetization reversal [≈ -37 Oe to be compared to $H_c \approx -60$ Oe: Fig. 2(c)]. When compared to Fig. 1(b), much more pronounced image intensity variations, hence wide amplitude magnetization fluctuations, are observed in the isolated Co layer. [The overall morphology of these fluctuations appears consistent with previous observations in ferromagnetically coupled multilayers,[1] although the spatial wavelength of the fluctuations proves to be smaller in the present case of a single Co layer.]

In samples made of a full spin-valve period, the thicknesses of the various layers have been tailored such as to solely gain information on the reversal of the top magnetic layer in a Kerr experiment (penetration depth of the light of the order of 200 Å). Conversely, VSM experiments are sensitive to both magnetic layers. Hysteresis loops measured from the symmetrical structures are qualitatively identical [Figs. 3(c) and 4(c)] although the coercive fields of the Co layers vary appreciably, probably a microstructure related phenomenon. The typical shapes of the hysteresis loops clearly indicate that the two magnetic layers are exchange uncoupled. Both VSM measurements and Kerr imaging experiments reveal strong changes in the magnetic properties of the NiFe layer. A significant increase of the NiFe coercive field is first detected (≥ 8 Oe, a value deduced from the minor hysteresis loop of Fig. 3c, to be compared to the 1.5 Oe value found in a single NiFe layer). Hence, independent of the variations in the Co layer coercive field, the coercive field of the NiFe layers amounts to 4–5 times the value typical of an isolated layer. Besides, Kerr imaging shows that magnetization reversal now takes place in the NiFe layer through the nucleation, under reverse field, of considerably smaller size domains. Domain nucleation proves quasihomogeneous, followed by some degree of domain collapse and merging whereas the typical domain size does not exceed a few microns. For instance, Fig. 3(a) exhibits in a $H \approx -14$ Oe reverse field, a finely subdivided domain pattern to be compared to the coarse structure in Fig. 1(a) pertaining to an isolated NiFe layer. Notwithstanding the change in the Co layers coercive field values, the domains observed in Fig. 3(a) prove to be still larger than those encountered in the hard (Co) layer of a full period [Fig. 4(a)]. The average domain size in a full stack always appears smaller than the corresponding quantity in a single Co layer [Fig. 2(a)]. The size of the smallest domains observed is comparable with the spatial resolution of the Kerr microscope, namely ≈ 3000 Å. Thus, they are made of only a few exchange coupled grains in these virtually untextured samples with grain sizes ranging from 500 to 1000 Å. Magnetization fluctuations of extremely high amplitude (as large as $\approx \pm 90°$) may be detected in the NiFe layer under proper illumination and polarization conditions [Fig. 3(b)]. The correlation between the patterns in Figs. 3(a) and 3(b) becomes more explicit when looking at Fig. 3(a) at glancing angle after rotating the Kerr micrograph by 90°. Magnetization fluctuations of very low amplitude are

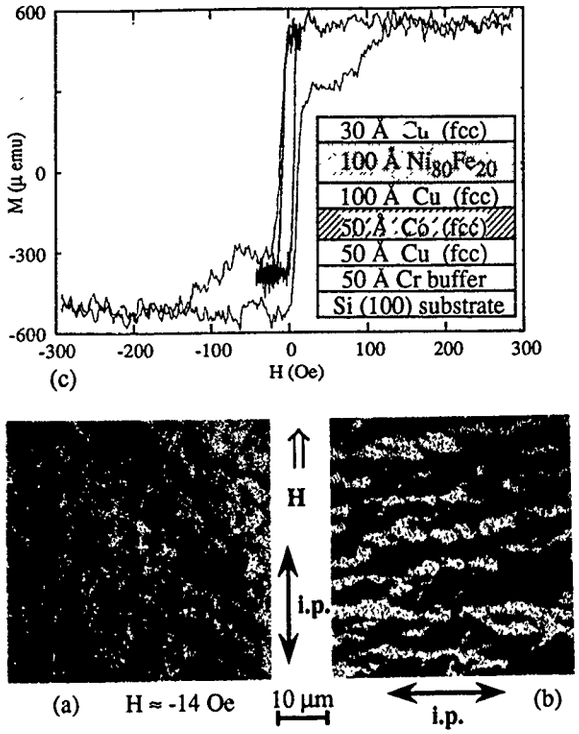

FIG. 3. Two similar domain structures generated under reverse **H** field ($H \approx -14$ Oe), observed in the NiFe layer of one spin-valve Cu/Co/Cu/NiFe/Cu full period. (a) Plane of incidence i.p.$\|\mathbf{H}$; (b) i.p.$\perp\mathbf{H}$; (c) is the corresponding hysteresis loop including the minor loop of the NiFe layer.

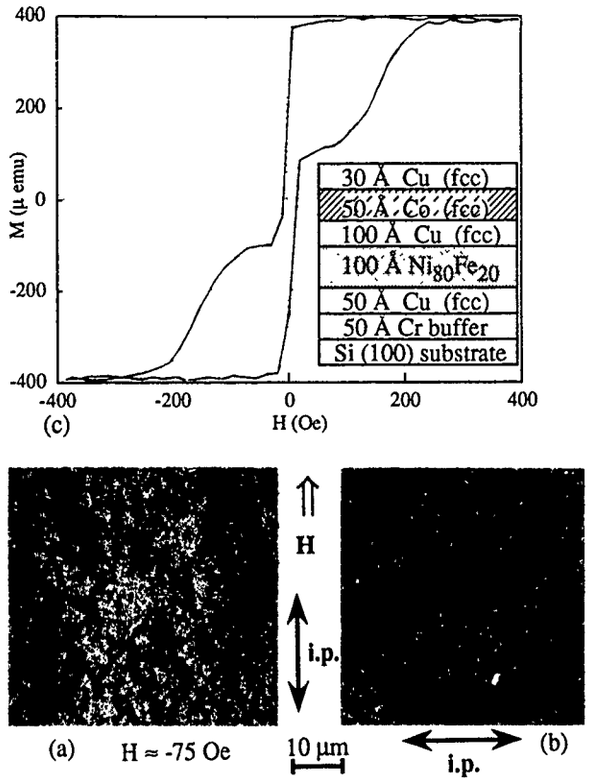

FIG. 4. Two similar domain structures generated under reverse **H** field ($H \approx -75$ Oe), observed in the Co layer of one spin-valve Cu/NiFe/Cu/Co/Cu full period. (a) Plane of incidence i.p $\|\mathbf{H}$, (b) i.p.$\perp\mathbf{H}$, (c) is the corresponding hysteresis loop.

first detected in the Co layer for applied field values as small as -15 Oe, a low value in comparison with the coercive field of the Co layer but close to the NiFe layer coercive field [≈ -14 Oe in Fig. 3(c)]. Fluctuations of higher amplitude are seen for larger field values, e.g., -75 Oe [Fig. 4(b)], a value close to the coercive field of the Co film.

III. DISCUSSION AND CONCLUSION

A clear increase of the coercivity of a "hard–soft"-type stack as a function of decreasing spacer thickness was brought into evidence by the work of Hill and McCullough.[3] For the system considered, any coupling effect seems to vanish for spacer thicknesses above ≈2000 Å. Such an experiment was not reproduced here. However, the thickness of the Cu spacer layers used in this work clearly lie above the threshold for indirect exchange coupling[6] and safely under the limit of dipolar coupling to be inferred from Ref. 3. It follows that the magnetization fluctuations detected in the NiFe layer may only be assumed to be linked to the fluctuations of moderate amplitude detected in the Co layer for field values close to the coercive field of the NiFe layer in a "hard–soft" environment. In more general terms, the observed phenomena appear to result from an interplay between microstructure and dipolar coupling across the 100-Å Cu spacer layer. A random 3D (2D) orientation of the cubic anisotropy axes in a nontextured ([111] textured) Co layer is bound to induce magnetization inhomogeneities in the hard layer, hence magnetization divergences which act as sources of stray field. One may be reminded that, at least in its hcp phase, the quality factor $K/2\pi M_s^2$ of cobalt is less than, but close to 1. Therefore, a regime of strong correlations between anisotropy driven magnetization fluctuations and dipolar interactions is anticipated to establish itself, even in a single Co film, as illustrated in Fig. 2.

In addition, the sputtering process promotes columnar growth, implying a high degree of coherence between the cubic axes of the fcc Co and fcc NiFe layers. Magnetization fluctuations in the soft layer thus should arise not only from magnetostatic interactions between the soft and hard layers, but also from the distribution of cubic anisotropy axes in the soft layer, with potentially different responses as a function of texturing.

Because of an anticipated strong correlation regime, perturbation approaches may hardly be considered as relevant. Although this work fails to provide some modeling of the observed phenomena, it clearly demonstrates the existence of macrofluctuations with a specific spatial wavelength range which appeals to a comparison with numerical simulation data in disordered, dipolar and/or exchange coupled media.

Observation of large biquadratic coupling of FeCo through Mn (invited) (abstract)

M. E. Filipkowski,[a] C. J. Gutierrez,[b] J. J. Krebs, and G. A. Prinz
U. S. Naval Research Laboratory, Washington DC 20375-5000

A new system, exhibiting unusually large interlayer biquadratic exchange coupling, has been discovered, consisting of single crystal FeCo/Mn/FeCo sandwiches epitaxially grown on GaAs substrates. Normalized $m(H)$ curves yield a remanent moment of approximately 0.5 for all cases studied, with a number of examples having saturation fields as large as several Tesla. This implies a biquadratic coupling constant as large or larger than many known bilinear coupling constants. None of the normalized $m(H)$ data exhibits a remanence of less than 0.5, indicating the absence of comparable contributions from bilinear coupling. Angular dependent FMR at 9 GHz implies a fourfold anisotropy of opposite sign to that measured for single FeCo layers, whereas FMR at 35 GHz agrees in sign with the single layer anisotropy. Detailed analysis of this contradiction shows that this is an apparent anisotropy reversal which emerges within the theory of FMR in the presence of large biquadratic coupling, requiring values of the coupling constant in excess of $-j_2=2$ ergs/cm^2, where the coupling term in the energy is written $J_2[(\mathbf{m}_1\cdot\mathbf{m}_2)/m_1m_2]^2$. This large biquadratic coupling, together with the absence of bilinear coupling, appears to contradict existing theories of interlayer exchange.

A mechanism resulting in biquadratic interlayer coupling is proposed and analyzed theoretically. This mechanism is connected with the magnetic dipole field, created by magnetic layers with roughness. This field decays exponentially with the distance from the layer, but it shows oscillating behavior in the lateral direction. The scale of both exponential and oscillating dependencies corresponds to the scale of the interface roughness and can reach 20–30 nm. The oscillating variation of the field makes 90° alignment of the magnetization energetically favorable in analogy to the Slonczewski's mechanism.[1] Computer simulations and estimates show that this mechanism can provide a coupling strength of the order of 0.01 erg/cm^2 for Fe films with 1 nm interlayer thickness. Sensitivity to magnetic atoms and low intrinsic absorption characterize the interaction of neutrons with matter. Consequently, polarized neutron reflectivity provides a unique means of performing depth-resolved vector magnetometry. We have used this technique to determine the magnetization depth profiles of Fe/Cr superlattices. Superlattices of bilayer composition [55 Å Fe/17 Å Cr], grown at 523 K, exhibit biquadratic coupling with large saturation fields (~3 kOe), while those grown at 293 K are ferromagnetically ordered. We have directly measured the evolution of the coupling angle between adjacent Fe layers as a function of applied field and will discuss how bilinear, biquadratic, and external field terms produce the observed order. The weaker coupling found in the Fe/Al system makes possible the investigation of a range of spin configurations at temperatures that do not endanger the sample. We have mapped the phase diagram of a [42 Å Fe/12 Å Al/39 Å Fe] (100) trilayer and find evidence of biquadratic coupling at low temperatures and fields (e.g., when $H=180$ Oe, the Fe layer spins relax away from ferromagnetic alignment below $T\approx170$ K). Our measurements agree qualitatively with energy minimization calculations and the results of bulk magnetometry.

Monte Carlo histogram calculation of the critical exponents of an $Fe_xMg_{1-x}Cl_2$ Ising model (invited)

Laura Hernández and H. T. Diep
Groupe de Physique Statistique, Université de Cergy-Pontoise, 49 Avenue des Genottes, B.P. 8428, 95806 Cergy-Pontoise Cedex, France

In a previous work, a realistic three-dimensional 3-D Ising model of $FeCl_2$ was studied. It consists of triangular lattice planes stacked along the c axis of the crystal, with the following interactions: a nearest neighbor (nn) ferromagnetic one competing with a next-nearest-neighbor (nnn) antiferromagnetic interaction, which causes some degree of frustration in the plane, the planes being weakly coupled by an antiferromagnetic interaction. In fact, the latter is a superexchange interaction, and we have taken into account all the equivalent superexchange paths in the sense of the Anderson rule, which amounts to 12 neighbors in each one of the adjacent planes. In this work we present the preliminary results of a study of the critical exponents of this model using the Monte Carlo histogram method and finite size scaling. The interest of such study lies in the layered structure of this system, which might have an effect on its effective dimensionality at the transition point, and also in the effects of frustration, as well as those of superexchange interactions on the critical exponents. We also show the results obtained by the same method, on the critical exponents of the diluted system in the zero and low magnetic field.

I. INTRODUCTION

$FeCl_2$ and $FeBr_2$ are prototype systems for the study of magnetic phase transitions since a long time ago. They show the outstanding feature of being associated to the different steps in the progress of the knowledge of this field. After the first results showing their metamagnetic character,[1] much effort has been done to describe their critical behavior. In particular, the experimental works of Jacobs and Laurence[2,3] and Vettier[6] have given a detailed description of their phase diagram in a magnetic field. Neutron scattering experiments[4–6] have provided us with the values of the relevant interaction constants.

Some theoretical Hamiltonian models showing this kind of metamagnetic phase transition have also been proposed. Harbus and Stanley[7] have performed a high temperature series expansion on a simple cubic lattice Ising model with in-plane ferromagnetic coupling and antiferromagnetic coupling of the planes (the "meta" model) and on the "nnn model"[8] consisting of a simple cubic Ising lattice with isotropic antiferromagnetic nearest neighbors (nn) and ferromagnetic next-nearest-neighbors (nnn) interactions.

Landau,[9] in a Monte Carlo study of antiferromagnetic Ising simple cubic and simple square lattices with nn antiferromagnetic and nnn ferromagnetic coupling, has also found a tricritical behavior.

However, all these models considered only the simplest lattice structures (square and simple cubic), without taking into account other features appearing in $FeCl_2$ and $FeBr_2$: high anisotropy, triangular lattice planes, superexchange paths along c axis, and in-plane frustration due to nnn antiferromagnetic interaction.

In 1979, Aharony and Fishman showed that an anisotropic antiferromagnetic system with bond dilution in a uniform magnetic field, has the same critical behavior as that of the random field Ising model (RFIM).[10] This statement was later extended by Cardy to anisotropic antiferromagnets with site dilution in a uniform magnetic field (DAFF).[11] This fact made $FeCl_2$ and $FeBr_2$ regain interest, as they constituted an excellent material for the experimental investigation of the RFIM.

Since then, a great experimental effort, as well as many theoretical studies, have been done. For instance, Soukoulis *et al.* and Grest *et al.* have tested the equivalence between DAFF's and RFIM in two and three dimensions[12,13] in simple square and simple cubic lattices with isotropic nn interactions. Diep *et al.*[14] and Galam *et al.*[15] have analyzed the existence of a tricritical point (TCP) as a function of dilution in a DAFF consisting of a simple cubic lattice with isotropic nn antiferromagnetic and nnn ferromagnetic interactions. Recently, a simulation on a highly diluted (50%) simple cubic lattice with isotropic antiferromagnetic nn interaction was performed by Nowak *et al.*,[16] with special attention paid to the high field region.

In spite of all this effort, many questions still remain open. For instance, while the existence of long range order (LRO) is admitted for a three-dimensional (3-D) RFIM,[17,18] it is still under discussion for some DAFF's because of the long relaxation times involved.[19–21]

Experimental studies show, in general, that the state of the system at a particular point of the temperature-field (T,H) space depends on the process used to take the system to that point. It seems reasonable to suppose that some of the unclear aspects found when comparing theoretical with experimental results may stem from the particularities of the real

 0021-8979/94/76(10)/7093/6/$6.00 © 1994 American Institute of Physics

system. For instance, the expected LRO as well as the shape of the magnetic domains (if any) formed while this (LRO) is being established, must be related to the kind of lattice considered, its spatial anisotropy, the existence of frustrated or competing interactions, its percolation threshold, etc.

In a previous work,[22] we have studied, by Monte Carlo simulations, the critical behavior of a $FeCl_2$ model. This model, though quite simple, kept the outstanding features of the system: high spatial anisotropy (triangular lattice planes stacked along the **c** axis), the superexchange paths for the interplane interaction, competing interactions, and frustration in the plane. The results we have obtained with such a model are in excellent qualitative and quantitative agreement with experimental ones.

Based on such a good description of the pure system, in a recent work we addressed our study to some of the experimental results on the diluted system that were not well understood. In particular, we studied the existence of a TCP and its behavior with dilution. We also studied the character of equilibrium temperature loops in a constant field (whether they are reversible or not) and the existence of a LRO for a field-cooling (FC) process. As mentioned above, irreversibilities in temperature loops have been experimentally reported. We have analyzed this fact by performing short simulations on our finite systems, showing that such irreversibilities correspond to a nonequilibrium effect. We have also investigated the experimental result stating that the magnetization issued from a FC process (m_{FC}) is greater than that issued from a field-heating (FH) one (m_{FH}).[20,21] We have determined the irreversibility line from the first temperature, where $m_{FC} > m_{FH}$ in a FC process, and we tried to elucidate the kind of magnetic domains formed in this irreversibility region that are responsible for that result.

We are now interested in determining the critical exponents of this system. Different questions may be asked on this topic. First, one may think that the layered structure of this system might affect its effective dimensionality, even in the pure case. Concerning the diluted system, the Harris criterion[23] states that when the specific heat exponent of the pure system is $\alpha > 0$, a small dilution may modify the critical behavior. In addition, renormalization group ϵ expansion treatments[24] show that a sharp transition may still exist, but with exponents different from those of the pure case. Finally, the application of a small uniform field to the diluted system in the strong concentration limit allows us to model an experimentally studied RFIM.

The article is organized as follows: in Sec. II we summarize the results obtained on these systems in our previous works; in Sec. III we describe the technical details concerning the present work; in Sec. IV we present the results on the critical exponents. Finally, in Sec. V we present our conclusions and discussions on forthcoming work.

II. PHASE DIAGRAM OF THE $Fe_x Mg_{1-x}Cl_2$ SYSTEM

A. Description of the model

Figure 1(a) shows the crystalline structure of the system determined by Wyckoff.[25] The Hamiltonian of the system may be written[26] as

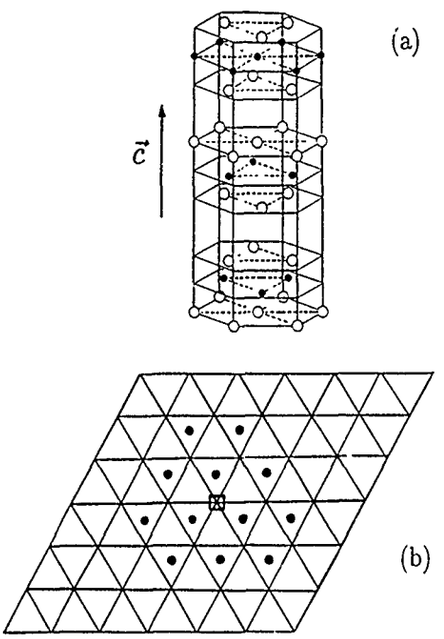

FIG. 1. (a) Crystalline structure of $FeCl_2$. (Ref. 25) ●, Fe^{2+}; ○, Cl^-. (b) Top view of the 12 neighbors of a Fe^{2+} ion □, the considered ion; ●, neighbors in the adjacent plane below.

$$\mathcal{H} = -J_1 \sum_{\langle nn \rangle} \eta_i \eta_j s_i s_j - J_2 \sum_{\langle nnn \rangle} \eta_i \eta_k s_i s_k - J' \sum_{\langle nn' \rangle} \eta_i \eta_l s_i s_l - g\mu_B H \sum_i \eta_i s_i , \quad (1)$$

where $s_i = \pm 1$ is an Ising spin; $\langle nn \rangle$ and $\langle nnn \rangle$ denote the sum over the nearest and next-nearest neighbors in the plane, respectively, and $\langle nn' \rangle$ indicates the sum over the interacting spins belonging to adjacent planes. As the latter is a superexchange one, we have taken into account all the equivalent magnetic paths for the coupling of iron planes via the chlorine ones. Following Anderson's rule, this leads to 12 neighbors in each one of the neighboring planes as is shown in Fig. 1.[22]

In order to simulate a given quenched disorder, we chose the sites at random and assigned to each site i one of the values of the corresponding occupation variable $\eta_i = 0,1$, with a probability $\mathcal{P}(\eta_i = 0) = p$, until we got $N_p = p \times N$ "vacancies" (N being the total number of sites and $p = 1 - x$ the desired amount of dilution).

The values of the interaction constants have been taken from Vettier's work.[6] As we have discussed in a previous work,[22] those values have been obtained fitting experimental data to a Hamiltonian that is different from Eq. (1). Thus, the relevant quantities are the ratios of the interaction constants, and not their absolute values. To simplify the comparison with experimental results on the diluted system, we have normalized these constants in the following way: we have performed simulations on the pure system, varying the values of the interaction constants but keeping their ratios fixed, until we reproduced the value of T_N given by Vettier.[6] Hence, we have a ferromagnetic nn interaction $J_1 = 6.74$ K, in com-

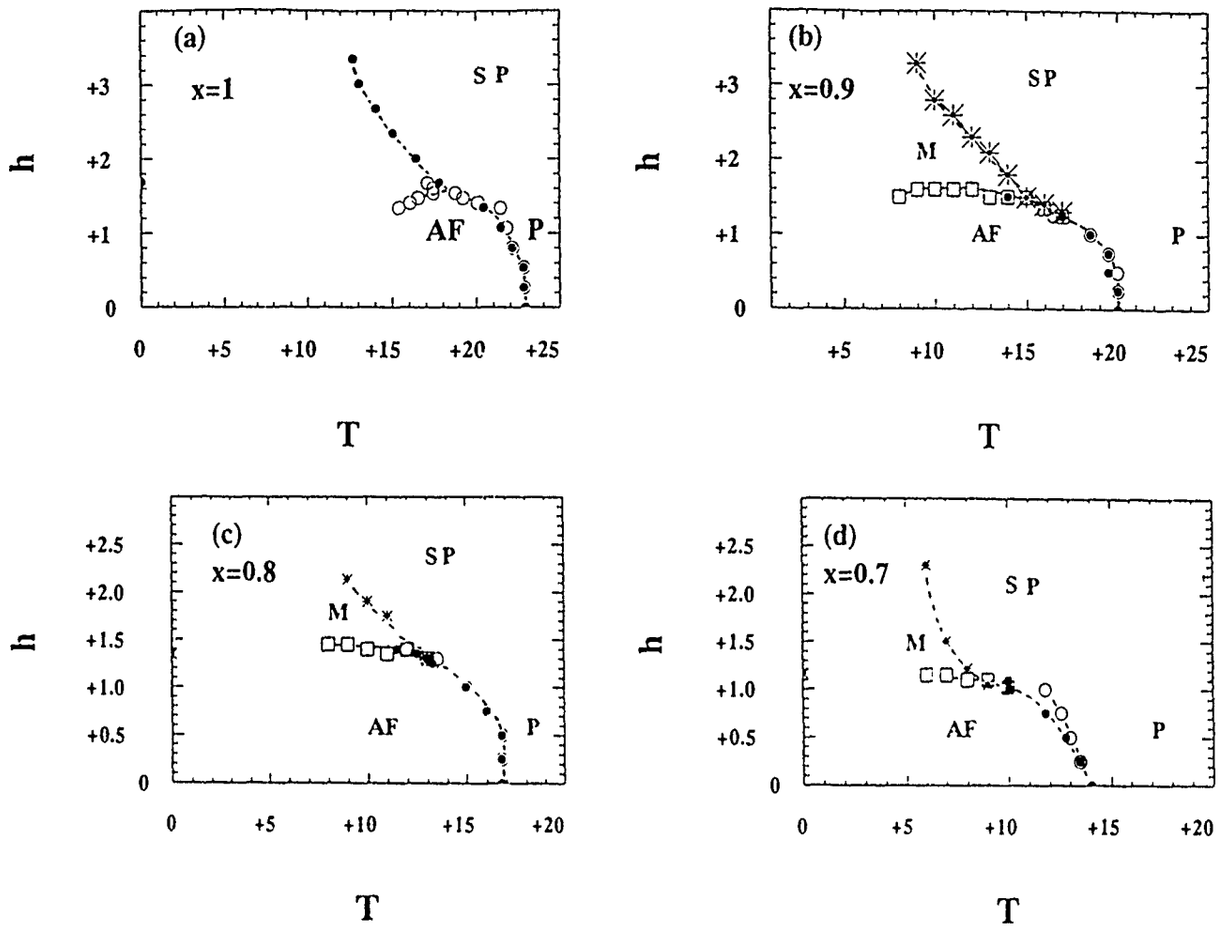

FIG. 2. Detailed cuts of the phase diagram along planes x = const. AF: antiferromagnetic phase; SP: saturated paramagnetic phase; P: paramagnetic phase; M: mixed region. petition with a frustrated antiferromagnetic nnn one, $J_2=-1.01$ K, and a superexchange antiferromagnetic interplane interaction, $J'=-0.07$ K.

In the following we will use the notation

$$h=g\mu_B H / k_B .$$

B. Summary of previous results

In general, we studied the following quantities: global magnetization per site m; staggered magnetization along the c axis m_{st}; energy per site E; specific heat c; susceptibility χ; staggered susceptibility χ_{st}; and Edwards–Anderson order parameter q. We aiso keep the last configuration of the lattice obtained at each point of the (T,h,x) space for further analysis.

For the pure system, we have shown that the transition is continuous for low fields, but becomes first order at a tricritical temperature T_t that can be estimated as the temperature where hysteresis in field loops disappears. We have found the ratio between the TCP temperature and the Néel temperature to be $T_t/T_N=0.87$, in excellent quantitative agreement with the experimental value $T_t/T_N=0.886$.[6]

The diluted system was studied by means of simulations of loops in temperature (FC–FH) at a constant field and loops in the magnetic field at a constant temperature ($h\uparrow-h\downarrow$). We have determined the phase diagrams in the (T,h,x) space for concentrations $x=0.9,0.8,0.7$. Our results show the existence of a TCP that is shifted to low temperatures as dilution increases. The values obtained for T_t as well as those obtained for T_N, compare quite well with experimental

TABLE I. Variation of T_t and T_N as a function of dilution. Comparison with experimental values.

x	T_t^{exp}(K)[a]	T_t^{MC}(K)	T_N^{exp}(K)[b]	T_N^{MC}(K)
1	20.5	19.9	24	22.9
0.9	16.5	15	20.5	20
0.8	13	12	17.6	16.75
0 7	8	7	13.6	14

[a]Reference 27.
[b]Reference 28.

ones.[27,28] The width of the hysteresis cycle is also found to decrease with dilution.

Figure 2 summarizes these results. It shows cuts of the phase diagram for different values of concentration x.

Table I gives the comparison of our results with experimental ones obtained by Wood and Day[27] and Bertrand *et al.*[28]

We have also studied fast FH+FC cycles to simulate, on a finite system, the long relaxation times observed experimentally, and we have found that, for low fields, the cycle is still reversible, while for $h \sim h_0(x)$, irreversibilities appear giving rise to $m_{FC} > m_{FH}$, in agreement with experimental results.[21] The irreversibility line T_{irr}, defined as the highest temperature where $m_{FC}=m_{FH}$, is coincident with $T_c(h)$ for low fields, but lies above it as the field approaches $h_0(x)$, in agreement again with experimental measurements. This line is shown in Fig. 2 for the $x=0.3$ case.

We have also investigated the shape of the magnetic domains formed in the irreversible region. Here the domains look like distorted pipes that are placed one beside the other, trying to keep an antiferromagnetic order along the **c** axis. In each plane, clusters of opposite orientation are separated by vacancies in order to avoid losing exchange energy.[26]

III. CRITICAL EXPONENTS

A. Technical description

The Monte Carlo histogram method[29–31] is known to be a very accurate way to determine critical exponents. It does not need a previous knowledge of T_c with an overwhelming precision, as it was the case with traditional Monte Carlo calculations of critical exponents.

We have used our previous results on this system to locate the temperature T_0 where the Monte Carlo simulation is performed. We have calculated the following quantities: staggered magnetization,

$$m_{st}=\langle \mu_{st} \rangle, \tag{2}$$

$$\mu_{st}=\frac{1}{N_k}\sum_{k=1}^{N_k}(-1)^{k+1}\frac{1}{N_i N_j}\sum_{ij} s_{ijk}, \tag{3}$$

where i,j are the subscripts in the plane and k is the subscript corresponding to the **c** axis. In the following, we will consider systems of equal number of sites in each direction, and we will denote their sizes by $L \times L \times L$.

Energy per spin,

$$E=\langle \mathcal{H} \rangle;$$

specific heat,

$$c=\frac{1}{k_B T^2}(\langle \mathcal{H}^2 \rangle - \langle \mathcal{H} \rangle^2); \tag{4}$$

staggered susceptibility,

$$\chi_{st}=\frac{1}{k_B T}(\langle \mu_{st}^2 \rangle - \langle \mu_{st} \rangle^2); \tag{5}$$

first-order cumulant of the order parameter,

$$V_1=\left\langle \frac{\partial \ln m_{st}}{\partial(1/k_B T)} \right\rangle = \frac{\langle m_{st} E \rangle}{\langle m_{st} \rangle} - \langle E \rangle; \tag{6}$$

second-order cumulant of the order parameter,

$$V_2=\left\langle \frac{\partial \ln(m_{st}^2)}{\partial(1/k_B T)} \right\rangle = \frac{\langle m_{st}^2 E \rangle}{\langle (m_{st}^2) \rangle} - \langle E \rangle. \tag{7}$$

The mean values, which are functions of m_{st} and of powers of E, may be calculated as a continuous functions of temperature using the histogram obtained at T_0 as follows:[31]

$$\langle E^n f(m_{st}) \rangle = \frac{\Sigma_E E^n \langle f \rangle(E) H(E) \exp[-\Delta K E]}{\Sigma_E H(E) \exp[-\Delta K E]}, \tag{8}$$

where $H(E)$ is the histogram measured at T_0 and $\langle f \rangle(E)$ are the mean values of the corresponding function of m_{st} calculated at T_0 for each *fixed value of the energy*.

For large values of the system of linear size L, these quantities are expected to scale with L as follows:

$$V_1 \propto L^{-1/\nu}, \tag{9}$$

$$V_2 \propto L^{-1/\nu}, \tag{10}$$

$$c_{H_{max}} = C_0 + C_1 L^{\alpha/\nu} \tag{11}$$

$$\chi_{st\,max} \propto L^{\gamma/\nu}, \tag{12}$$

$$m_{st}[T_c(\infty)] \propto L^{-\beta/\nu}, \tag{13}$$

$$T_c(L) = T_c(\infty) + C_A L^{-1/\nu}. \tag{14}$$

Having a certain knowledge about the location of T_c helped us to neglect, in this first approach, corrections to scaling. In addition, as our smallest size is $L=12$, corrections to finite size scaling have also been neglected.

We have estimated ν independently from Eqs. (9) and (10). With these values, we calculate γ from Eq. (12). We have then estimated $T_c(\infty)$ by extrapolating Eq. (14) for each observable. Using this value of $T_c(\infty)$, we calculate β from Eq. (13). The Rushbrooke scaling law $\alpha+2\beta+\gamma=2$ allows us to obtain α. Finally, using the hyperscaling relationship, we can estimate the effective dimension of this model, $d=(2-\alpha)/\nu$.

B. Analysis of results

1. The pure system

We have performed a Monte Carlo histogram calculation for lattices of linear sizes $L=12$, 18, 24, and 30 at the temperature T_0 near the T_N obtained in our previous study. Figure 3(a) shows the finite size scaling study of staggered magnetization cumulants done over the first three lattices. The value obtained is $\nu=0.59\pm0.03$.

Figure 3(b) shows the fit of Eq. (12) to our data. We get a value $\gamma=1.19\pm0.08$.

The determination of β needs an estimation of the critical temperature of the infinite lattice. It has been extrapolated from the behavior of the extrema of different observables as a function of $L^{-1/\nu}$. We have found 23.12 ± 0.03 K. The fit shown in Fig. 3(c) gives $\beta=0.27\pm0.04$.

Using the Rushbrooke relationship, we obtain $\alpha=0.27\pm0.10$.

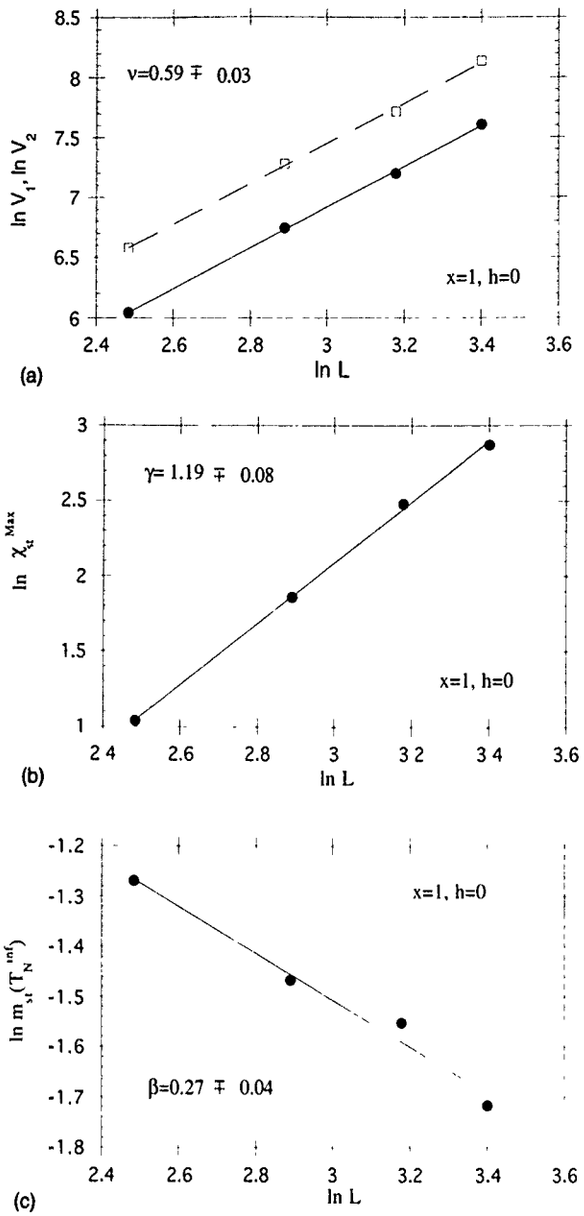

FIG. 3. $x=1$, $h=0$. (a) $\ln V_1$(●), $\ln V_2$(□) vs $\ln L$: determination of ν, (b) $\ln \chi_{st}$ vs $\ln L$: determination of γ. (c) $\ln m_{st}[T_N(\infty)]$ vs $\ln L$· determination of β.

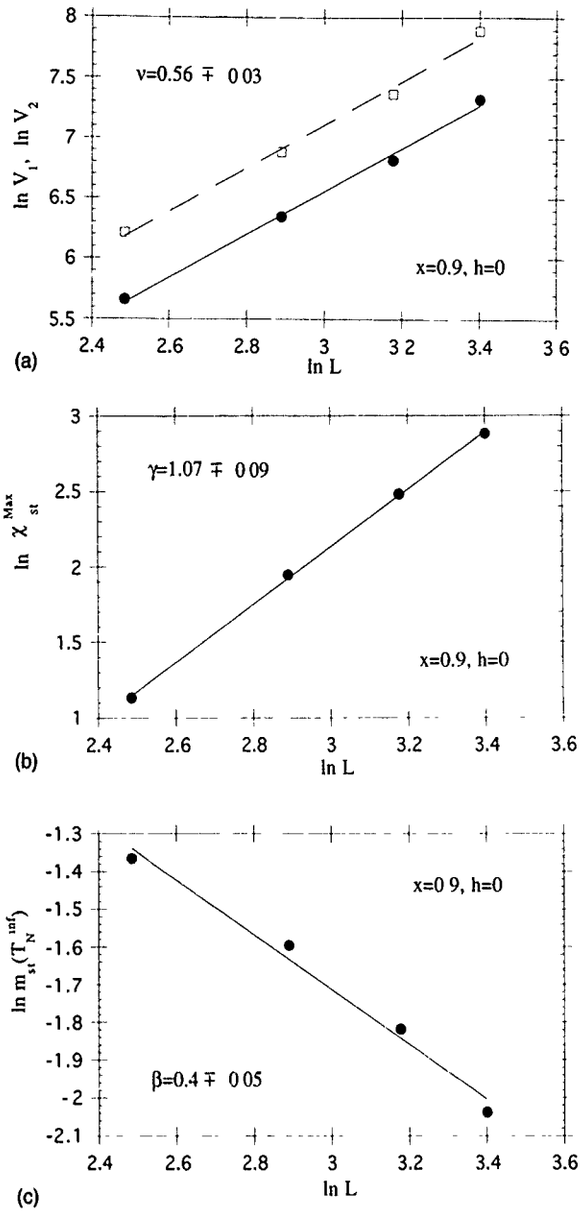

FIG. 4 $x=0.9$, $h=0$ (a) $\ln V_1$(●), $\ln V_2$ (□) vs $\ln L$. determination of ν, (b) $\ln \chi_{st}$ vs $\ln L$· determination of γ, (c) $\ln m_{st}[T_N(\infty)]$ vs $\ln L$: determination of β.

With these values, the hyperscaling relationship gives an effective dimensionality of $d_{\text{eff}}\sim 2.93$. This shows that the layered structure of the system does not affect its effective dimension, even in the case of a quite weak interlayer coupling.

The set of critical exponents obtained above does not exactly correspond to that of the 3-D Ising model,[24] although some of them are rather close to it within the error margin. Surprisingly, this set is found to be similar to the results obtained for the frustrated 3-D Heisenberg spin systems.[32,33]

2. The diluted system

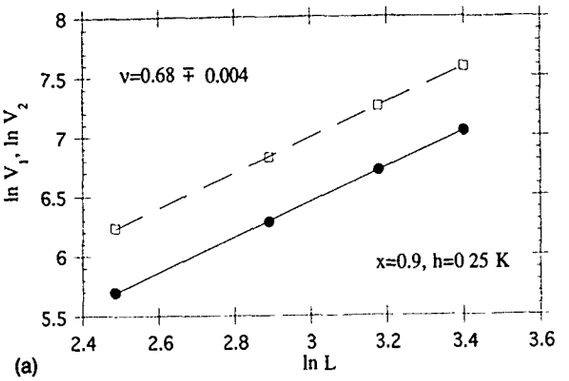
In this first approach, we have studied a system with a small dilution $p=0.1$. The results shown have been obtained for systems of linear sizes $L=12$, 18, 24, and 30. The fit of V_1 and V_2, shown in Fig. 4(a) gives $\nu=0.56\pm0.03$, lower than the value obtained for the pure system.

From the fit shown in Fig. 4(b), we get $\gamma=1.07\pm0.09$, again lower than the value obtained above.

The extrapolated value for the temperature of the infinite diluted lattice is $T_N(\infty)=20.27\pm0.03$ K, which gives $\beta=0.36\pm0.07$ [Fig. 4(c)].

When applying a uniform magnetic field to the diluted system, the correlation length exponent is clearly increased. On the contrary, the other exponents are less affected, for the studied fields, $h=0.25$ K and $h=0.5$ K, which correspond to a quarter and a half of the corresponding threshold field for this dilution.

Figure 5(a) shows the fit of Eqs. (9) and (10), which gives $\nu=0.68\pm0.005$ for the case $h=0.25$ K. The fit of Eq.



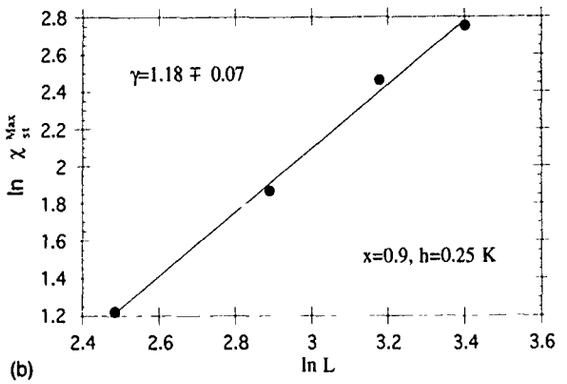


FIG. 5. $x=0.9$, $h=0.25$. (a) ln V_1 (●), ln V_2 (□) vs ln L. determination of ν, (b) ln χ_{st} vs ln L: determination of γ.

(12) [Fig. 5(b)] gives $\gamma=1.18\pm0.07$, which is similar within the error margin to the zero field case.

The determination of the remaining critical exponents proves to be more difficult in the nonzero magnetic field. In fact, the value of $T_N(\infty)$ obtained by extrapolation has a considerable uncertainty. We obtain $\beta=0.36\pm0.07$ and we derive from the Rushbrooke scaling law, $\alpha=0.1\pm0.04$ for $h=0.25$ K.

For $h=0.5$ K, the values of ν and γ remain unchanged (see Table II). As discussed above, the uncertainty on $T_N(\infty)$ is so large to prevent us from determining β.

IV. CONCLUSION

We have performed a preliminary study of the critical exponents of a $Fe_xMg_{1-x}Cl_2$ model. We have observed that the small degree of frustration due to nnn in-plane antiferromagnetic interaction and dominant nn in-plane interactions, as well as the superexchange between planes, are enough to cause a deviation of the critical exponents from those of the 3-D Ising model, even in the pure case. These exponents are closer to those of 3-D frustrated systems (antiferromagnetic stacked triangular lattices with Heisenberg spins) than those of the nonfrustrated 3-D Ising model.

We have also found that for this system of weakly coupled layers, the effective dimension remains 3. As soon as additional disorder is added to the system by means of simple dilution, critical divergences are reduced. This is seen by examining the values of ν, γ, and α given in Table II.

When applying a uniform magnetic field the diluted system is expected to behave like a RFIM. However, the results obtained do not correspond to those predicted for the 3-D RFIM.[35,36] This work shows that it is not obvious that the $Fe_xMg_{1-x}Cl_2$ system belongs to the RFIM universality class.

Further work concerning higher dilutions at different fields is in progress.

We summarize the previous results in Table II.

Simultaneous surface and bulk magnetic properties investigations by using simultaneous gamma, x-rays and conversion electron Mössbauer spectroscopy: Method and experimental results

A. S. Kamzin, L. A. Grigor'ev, and A. F. Ioffe
Physico-Technical Institute RAS, St. Petersburg 194021, Russia

The surface and bulk phase transitions in a microscopic antiferromagnetic Fe_3BO_6 crystal was investigated by means of new method: Simultaneous gamma rays, x-rays, and electron Mössbauer spectroscopy (A. S. Kamzin, V. P. Rusakov, and L. A. Grigor'ev, in Proceedings of the International Conference "Physics of transition metals," USSR-1988, Part 2, p. 271; A. S. Kamzin, and L. A. Grigor'ev, Pisma Zh. Tekh. Fiz. **16**, 38 (1990) [Sov. Tech. Fiz. Lett. **16**, 417 (1990)]), which makes it possible to study simultaneously the surface and volume properties of a bulk crystal.

I. INTRODUCTION

At the spin-reorientation phase transition (SRPT), it was observed that (1) the first-order SRPT transition in the volume of the crystal is accompanied by second-order reorientation of spins on the surface of crystal; (2) toward the surface of the crystal the temperature interval of the SRPT are increasing and no displacement of the center of the transition region is observed; (3) outside the SRPT region, the direction of the magnetic moments on the surface are different from in the volume of the crystals, and differences are increasing to the surface in the limit of the "transition" layer.

It was found that (1) the Neel temperature for the surface is lower than for the bulk; (2) there exists a surface layer of "critical" thickness, within which the transition temperature $T_N(L)$ increases with a distance from the surface and reaches at the lower (from the surface) boundary of the "critical" layer the value of Neel temperature for the volume of the crystal.

In order to understand surface phenomena, so as to determine how surface and bulk properties are related to each other, it is necessary to investigate the surface of bulk crystals in comparing with investigations of volume properties of that material, as well as the profiles of the properties (layer by layer analysis) of the surface layer. For this aim the experimental methods are very useful, which give us the possibility to study the surface and the bulk properties of massive crystals simultaneously. We have shown[1] that the Mössbauer effect measurements are simultaneous by detecting gamma rays in the transmission geometry, and conversion x-rays and conversion electrons in the backscattering mode are very suitable in each case.

In the present paper, we describe (1) new method (simultaneous gamma rays, x rays, and electron Mössbauer spectroscopy), which have been offered and used in Ref. 1 and that gives us the possibility to investigate the surface and bulk properties simultaneously; (2) results of investigations of the surface magnetic system behavior at the phase transitions (the Neel temperature as well as the spin-reorientation phase transition) in the bulk of crystal.

II. METHOD OF SIMULTANEOUS GAMMA RAYS, X RAYS, AND ELECTRON MÖSSBAUER SPECTROSCOPY

In the "classical" Mössbauer spectroscopy (MS) in the transmission mode (TMS) the γ rays permeating the sample are detected, thus giving information on the whole volume of the bulk samples. After absorption, the deexcitation radiation of nucleation in the absorber are the γ rays, the conversion, and Auger electrons (CED), and characteristic x rays (CX). Mössbauer spectroscopy CX (CXMS) allows us to study the properties of a few μm thick layer of a bulk crystal. In the case of Mössbauer spectroscopy with detection CE (CEMS), the information is extracted from a ~300 nm (for Fe^{57}) surface layer on the bulk sample.

The method of simultaneous gamma rays, x rays, and electron Mössbauer spectroscopy proposed in Ref. 1 combines these three modifications of Mössbauer effect measurements. The universal detector[2] and Mössbauer spectrometer constructed around the universal detector (Fig. 1) makes it possible to obtain the Mössbauer spectra immediately by detecting the γ rays, characteristic x rays, and secondary electrons, thereby simultaneously studying the properties of the

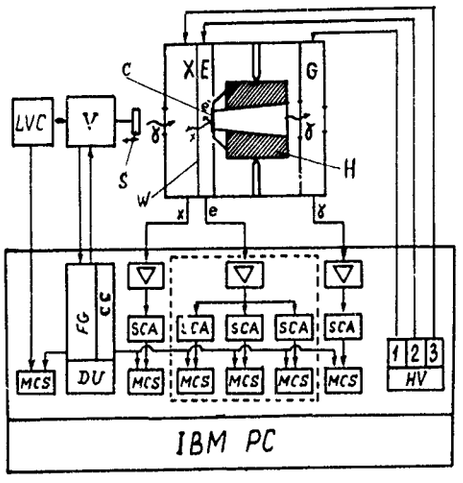

FIG. 1. Universal detector and block diagram of the system for the simultaneous gamma, x rays, and electron Mossbauer spectroscopy

volume and surface layers of bulk crystal. The γ rays emitted by a Mössbauer source (S) pass through the sample (C), through a hole in the heater (H), and are detected in chamber *G*. The sample is located in chamber *E*, and CE emitted from the sample are detected right in that chamber. The CX rays, after leaving the sample, pass through a beryllium foil (W) that separates counters *E* and *X*, and are detected in chamber *X*. Therefore chamber *E* detects only the conversion electrons, counter *X* detects only the conversion x rays, and chamber *G* detects only gamma quanta. This method of investigation was later called simultaneous triple radiation Mössbauer spectroscopy.[3]

It is known that the energy of an electron that has go out from the sample depends on the distance from the surface of the atom in which this electron was formed. Our electron counter has quite a good resolution, and by using discriminators (SCA in Fig. 1) we have the possibility to choose the electrons in a definite energy group.[4–6] Taking into account the probability that an electron reaches the surface of the crystal, it is possible to investigate the properties of a thin layer located at a definite depth from the surface. When a proportional detector is employed, the location of the layer and its thickness are not determined as accurately as with the electrostatic, or magnetic energy analyzer. However, a proportional detector is much more efficient, and thus has certain advantages.

It is not difficult to detect electrons at room temperature, but difficulties arises when the measurements are made above or below room temperature, because the sample is located inside counter E. In the universal detector, the furnace heats only the sample, but not the ambient gas. This is achieved by the multilayer heat insulation of the heater and also by its housing on needle supports. Liquid nitrogen vapor passes along the heat guide to take measurements at the region below room temperature. Thus, we have possibility for measurements in the interval from 100–750 K, with the accuracy of 0.03°–0.2°, depending on the measurements region.

To diminish the dead time of the storage system (MCS) we set the input pulse duration less than two buffer counters with checking before switching.[7] The form of motion of the Mössbauer source is controlled by the standard feedback (FG) signal. We have offered[7] to use an other optional controlling signal (CC), which is generated by adding the error signal averaged over 100–1000 periods to the current error signal. A given motion is provided with the accuracy of not greater than 0.03%.

The important advantage of the method, of simultaneous gamma rays, x rays, and electron Mössbauer spectroscopy[1] is that information from the bulk and surface of a macroscopic crystal is extracted: (1) simultaneously under identical conditions of the sample; (2) by using one method of investigation (the Mössbauer effect), which makes it possible to compare experimental results on surface and bulk properties strictly.

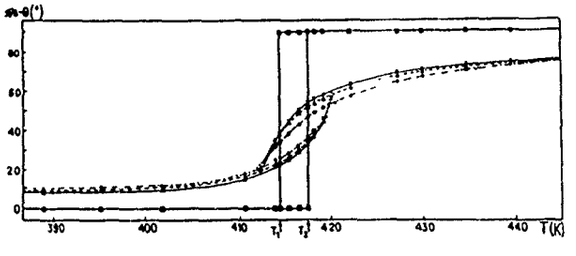

FIG 2. Experimental plots of the angle θ versus temperature in the volume (■) and surface layers of the Fe_3BO_6 crystal. Layer thickness (±10 nm): 0–40 nm (○); 50–90 nm (▽); and 150–200 nm (×).

III. INVESTIGATION OF THE SURFACE AND BULK SPIN-REORIENTATION PHASE TRANSITION IN ANTIFERROMAGNET Fe_3BO_6

We have studied the magnetic structure and SRPT in a surface layer and in a volume of a bulk crystal Fe_3BO_6 by using the new experimental method described above in Sec. II and in Ref. 1.

Surface studies were conducted on crystals chemically polished for ~50 h at room temperature in 1:1 mixtures of H_3PO_4 and H_2SO_4 acids. The experimental Mössbauer spectra obtained below and above the SRPT temperature $T_R = \sim 415$ K consist of two sextuplets, corresponding to iron ions in 8*d* and 4*c* positions. In the SRPT region, experimental spectra consist of the superposition of lines observed at the temperature below and above the SRPT temperature. The lines corresponding to different phases are well resolved, which makes it possible to investigate the behavior of the magnetic moments of each position and phase.[8]

The angle θ determining the direction of the magnetic moments, with respect to the wave vector of the γ rays, were found from the ratios of the intensities of the second and first (fifth and sixth) lines of the Zeeman sextuplets, using formula $I_{2,5}/I_{1,6} = (4 \sin^2\theta)/3(1+\cos^2\theta)$. The temperature dependence of this angle is displayed in Fig. 2.

It is evident from Fig. 2 that the magnetic moments in the volume of the crystal are oriented only the two values, 0 or $\pi/2$. In the SRPT temperature range, these two phases coexist. This results prove convincingly that SRPT in the volume of Fe_3BO_6 crystals occurs as a first-order phase transition in a temperature range from T_1 up to T_2.

The magnetic moments on the surface layers outside the region of SRPT tilt away from the directions along which the moments are oriented in the volume of crystal. The tilting angle, increases as the surface or the SRPT is approached. In the SRPT region, in a surface layer, the angle θ varies continuously from one value to another.

The theoretical studying of the problem of a spin-reorientation phase transition (SRPT) on a surface showed that the shape of the temperature hysteresis loop must change.[9] Comparison with theoretical results[9] reveals that the experimental data are in good agreement.

IV. THE SURFACE AND BULK MAGNETIC PROPERTIES OF THE ANTIFERROMAGNET Fe_3BO_6 NEAR THE NEEL TEMPERATURE

Analysis of the experimental spectra of Fe_3BO_6 near the Neel temperature showed that they can be divided into four

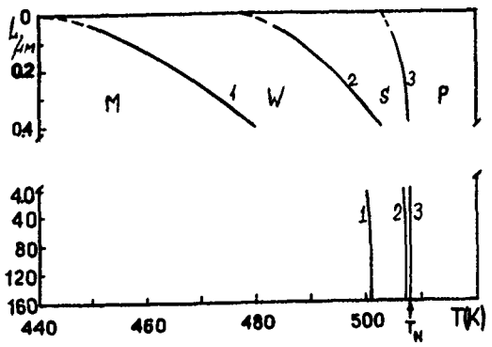

FIG. 3. Phase diagram of Fe_3BO_6 near the Neel temperature. One-boundary line $T_W(L)$; $2-T_s(L)$; and $3-T_N(L)$.

characteristic groups:[10] M, W, S, and P (see Fig. 3, where L is distance from the surface). The M spectra consist of two Zeeman sextuplets, P spectra—of two quadruple doublets. This means that the material in the M region is magnetic, in the P region—in the paramagnetic state. In region W, the widths of the outer lines of the sextuplets increases up to the $T_N(L)$, the width of the inner lines do not change. The experimental spectra observed in the S region consist of a superposition of lines of the paramagnetic doublets of the P phase on the spectra of the W phase. As the temperature increases from $T_c(L)$ to $T_N(L)$, the intensities of outer lines decrease and at the $T_N(L)$ these lines vanish. In those temperature intervals, intensity of inner lines increases.

In summary, analysis of the experimental results has shown that as the temperature increase in some sections paramagnetic regions arise directly on the surface of the crystal. As the crystal is heated further, the paramagnetic regions on the surface expand and penetrate deeper into the crystal. At a certain temperature below the Neel point for the bulk of the crystal, the entire surface becomes paramagnetic, and with increasing temperature, deeper layers transform into the paramagnetic phase. At the Neel point the magnetic order destroys the entire remaining volume of the crystal. Thus, there exist a surface layer of "critical" thickness, in which the transition temperature $T_N(L)$ increases with a distance L from the surface and reaches at the lower (from the surface) boundary of the "critical" layer the value of T_N, corresponding to the volume of the crystal.

Magnetic properties of Fe_xCu_{1-x} granular alloy films

Peng Chubing, Chen Haiying, Li Guozhong, and Dai Daosheng
Department of Physics, Peking University, Beijing 100871, People's Republic of China

The magnetic properties of the Fe_xCu_{1-x} granular system, as functions of iron particle size, were studied. Using high resolution transmission electron microscopy, iron particle size was determined to be ranged from 1–4 nm in as-deposited samples as $x=0.06$–0.34. Magnetic measurements revealed that samples exhibit superparamagnetic relaxation below 300 K as $x\leqslant 0.22$. At 1.5 K, the average magnetic moment per each iron atom is reduced as the average number N of iron atoms in a particle is less than 450, and approaches the value of bulk iron as $N\geqslant 600$. Moreover, the temperature dependence of magnetization for Fe–Cu granular alloys was found to obey the Bloch's $T^{3/2}$ law below 300 K as $x>0.22$. We suggest that spin wave excitations of long wavelength occur due to the weak exchange coupling among iron particles as $x>0.22$. This behavior was confirmed by the ferromagnetic resonance study.

I. INTRODUCTION

The studies of surface magnetism of ferromagnetic materials have discovered that the magnetic moment of surface atoms such as Fe(110) and Ni(111) is enhanced.[1,2] This behavior was also observed in multilayered thin films (e.g., Fe/Ag,[3,4] Co/Pd.[5] and Co/Pt[4,6]). It is very interesting whether magnetic moment of the ferromagnetic particles, such as Fe, Co, and Ni, is enhanced when its size is reduced. In recent experiments,[7–9] the magnetic behavior of Fe and Co clusters containing several tens to hundreds of atoms has been investigated by using the Stern–Gerlach method. It was found that the average effective moment in Fe and Co clusters was below that of bulk Fe and Co, respectively. Chien *et al.*[10] have studied the magnetic properties of iron particles in the Fe–SiO_2 granular films, and pointed out that the coercivity of those films was enhanced. It was also reported that the ferromagnetic, superparamagnetic, spin-glass, and cluster-glass behaviors exist in granular alloys.[11] In this paper, the magnetic properties of Fe_xCu_{1-x} granular films, including superparamagnetic behavior, effective exchange coupling, and the low-dimensional effect, were discussed.

II. EXPERIMENTS

Fe_xCu_{1-x} films were prepared by thermal co-evaporation method in a vacuum of 2×10^{-7} torr onto glass substrates cooled by liquid nitrogen. Thicknesses of films are about 500 nm. The iron volume fraction x was determined to be 0.06, 0.10, 0.13, 0.16, 0.20, 0.22, 0.24, 0.26, 0.28, 0.30, and 0.34 by electron energy spectrum analyses. The structure of films was characterized by electron diffraction and high resolution transmission electron micrograph (TEM). Magnetization curves for all samples at different temperatures were measured by a LDJ 9500 vibrating sample magnetometer (VSM). The ferromagnetic resonance measurements for samples with $x=0.16$ and 0.30 were carried out by using an electron paramagnetic resonance spectrometer working at x-band (9.8 GHz) at room temperature.

III. RESULTS AND DISCUSSIONS

Figure 1 displays the electron diffraction pattern and central dark-field micrograph for $Fe_{0.22}Cu_{0.78}$ film. In the diffraction pattern, (111), (200), (220), and (311) reflections of fcc Cu and (200), (211), and (220) reflections of bcc Fe appear, indicating that iron particles have precipitated from the film and form the bcc structure. In the TEM image, one can see that iron particles are very small, about 2.3 nm in diameter, and dispersed homogeneously in the film.

Figure 2 shows magnetization curves for Fe_xCu_{1-x} films with $x=0.10$, 0.16, and 0.22. It is seen that samples exhibit superparamagnetic relaxation below room temperatures as $x\leqslant 0.22$. In the superparamagnetic state, the effective magnetic moment μ_{eff} for Fe–Cu samples in the magnetic field H at temperature T is given by[10]

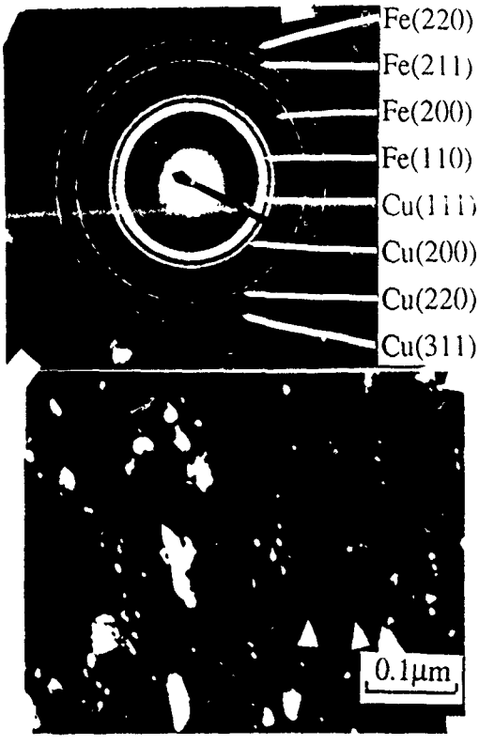

FIG. 1. Electron diffraction pattern and dark-field micrograph for as-prepared $Fe_{0.22}Cu_{0.78}$ film. The iron clusters are indicated by arrows.

 0021-8979/94/76(10)/7102/3/$6.00 © 1994 American Institute of Physics

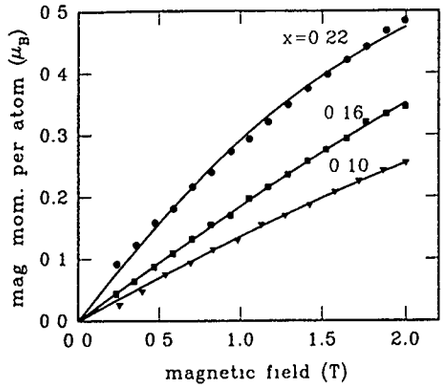

FIG. 2. Effective magnetic moment μ_{eff} per iron atom as a function of magnetic field for Fe–Cu films with $x=0.10$, 0.16, and 0.22 at $T=160$, 236, and 300 K, respectively. The solid lines are the theoretical curves obtained with Eqs. (1)–(2) with $\bar{D}=11.3$ Å, $\sigma=1.05$ for $x=0.10$; $\bar{D}=13.6$ Å, $\sigma=1.10$ for $x=0.16$ and $\bar{D}=22$ Å, and $\sigma=1.255$ for $x=0.22$.

$$\mu_{\text{eff}}=\int \mu L(v)f(v)dv, \tag{1}$$

where $L(v)$ is the classical Langevin function, $f(v)$ is the size distribution function, v is the volume of iron particles, and μ is the magnetic moment per iron atom in a cluster. For simplicity, the lognormal distribution function for spherical iron particles with diameter D is assumed,

$$f(D)=\exp[-(\ln D-\ln \bar{D})^2/2(\ln \sigma)^2]/\sqrt{2\pi}\ln \sigma. \tag{2}$$

By fitting the experimental data using Eqs. (1) and (2), the average diameter $\bar{D}$ and the width σ are estimated. For the $x=0.22$ sample, $\bar{D}=22$ Å and $\sigma=1.155$, in agreement with the TEM observation. From the $\bar{D}$ value, the average number N of iron atoms in a cluster for Fe–Cu samples can be determined and listed in Table I.

Figure 3 plots the average magnetic moment μ at 1.5 K as a function of the average number N for Fe–Cu samples. It can be seen that the magnetic moment of iron atoms increases rapidly with N as $N<450$, and approaches $2.2\mu_B$ as $N>600$. This reduction of μ as $N<450$ may result from the d–s electron hybridization on the interfaces between Fe particles and the Cu matrix.[12] Since the ratio of surface iron atoms to volume increases with the decreasing particle size, the average magnetic moment of iron clusters is hence reduced.

Figure 4 gives the temperature dependence of magnetization $\mu(T)$ for Fe_xCu_{1-x} samples with $x=0.10$, 0.13, 0.22, and 0.28. As $x\leqslant 0.22$, $\mu(T)$ decreases linearly with the increasing temperature below the blocking temperature. Such a linear dependence of magnetization is often associated with two-dimensional (2-D) magnetic behavior. At $x=0.28$, $\mu(T)$ can be fitted to the equation

TABLE I. The average number N of iron atoms in a cluster at each volume fraction x.

x	0.06	0.10	0.13	0.20	0.22	0.24	0.27	0.30	0.34
N	34	103	297	396	470	495	653	740	940

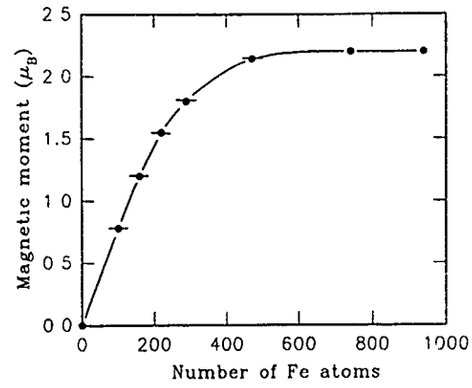

FIG. 3. The size dependence of the magnetic moment per iron atom for Fe–Cu film at $T=1.5$ K.

$$\mu(T)=\mu_0(1-BT^{3/2}), \tag{3}$$

which describes the thermal spin-wave excitations (Bloch's $T^{3/2}$ law). Obviously, it is hardly possible to excite a long-wavelength spin wave in an individual iron particle with size of about 3.0 nm. As iron concentration x is larger than about 0.24, a magnetic percolation effect sets in. By fitting the experimental data to Eq. (3), the Bloch constant B is obtained to be 1.34×10^{-4} $K^{-3/2}$. This B value is much larger than that for the bulk iron (about 3.5×10^{-6} $K^{-3/2}$). We suggest that an effective exchange interaction among single-domain iron particles appears for a Fe–Cu granular system with $x\geqslant 0.28$, leading to the excitation of a long-wavelength spin wave in the whole film. Since the Bloch constant is related to the exchange energy constant, then we deduce that the effective exchange constant is about one order less than that of the bulk iron. There is other evidence that may support the above suggestion. Figure 5 shows resonance field H_{res} vs the orientation ϕ_H of the applied dc magnetic for Fe–Cu samples, with $x=0.16$ and 0.28 at 300 K. For the $x=0.16$ sample, the magnitude of H_{res} is almost independent on the orientation, reflecting very little shape anisotropy. This very small angular variation of H_{res} results from the uniform precession of individual iron particles with spherical shape in the film. However, at $x=0.28$, the H_{res} value in-

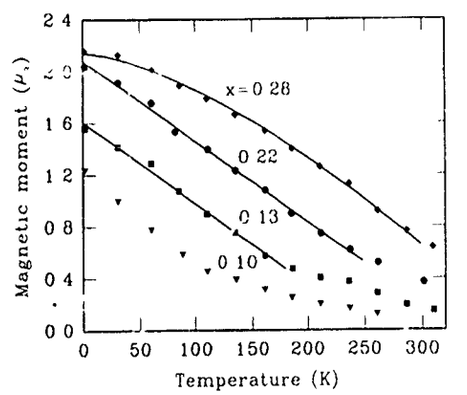

FIG. 4. The temperature dependence of the effective magnetic moment of iron clusters for Fe–Cu films with $x=0.10$, 0.13, 0.22, and 0.28. The solid lines are the fitted curves.

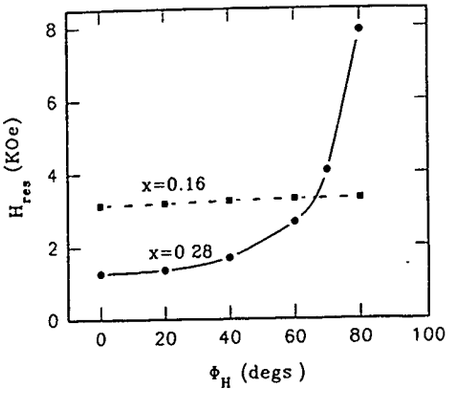

FIG. 5. The resonance field H_{res} as a function of angle ϕ_H between the dc magnetic field and the film plane for Fe–Cu granular films, with $x=0.16$ and 0.28.

creases rapidly with the ϕ_H value. This variation corresponds to the behavior of a ferromagnetic thin film dominated by shape anisotropy,[13] confirming the existence of effective exchange interaction among iron particles.

IV. CONCLUSIONS

The structural and magnetic properties of Fe_xCu_{1-x} granular alloys have been studied. The superparamagnetic behavior exists in a Fe_xCu_{1-x} granular system below 300 K as $x \leqslant 0.22$. At 1.5 K, the average magnetic moment of iron atoms decreases rapidly as iron particle size decreases. This behavior is understood by the hybridization of the $d-s$ electron on the surface of iron cluster. The appearance of long-wavelength spin wave excitations at low temperature and the ferromagnetic resonance experiment confirm that the weak exchange coupling exists among iron particles as $x>0.22$.

New possibilities offered by high resolution Fourier transform spectroscopy in studying magnetic phase transitions

M. N. Popova
Institute of Spectroscopy, Russian Academy of Sciences, 142092 Troitsk, Moscow Region, Russia

High resolution optical absorption spectra of an intrinsic R^{3+} ion or Er^{3+} probe were measured in cuprates $R_2Cu_2O_5$ and R_2BaCuO_5 related to high T_c superconductors of the 123 type and in low-dimensional nickelates R_2BaNiO_5. We have registered for the first time phase transitions, some of them not detectable by other methods, in R_2BaCuO_5 with R=Y, Lu, Nd, Dy, Yb, and Lu, in R_2BaNiO_5, with R=Nd, Sm, Eu, Dy, Ho, Tm, and Lu. Coexistence of two different magnetic phases in Y_2BaCuO_5 and Lu_2BaCuO_5 in a broad temperature range was demonstrated. Fine splitting of the low temperature magnetic phase transition, possibly caused by the interaction of critical fluctuations, has been observed in Dy_2BaCuO_5. Low-dimensional correlations at temperatures higher than the temperature of three-dimensional (3-D) magnetic ordering have been analyzed in quasi-2D compounds $R_2Cu_2O_5$ and quasi-1-D R_2BaCuO_5. We developed the method of the Er^{3+} probe in a series of isostructural $f-d$ compounds to select the right magnetic structure of an ordered d subsystem from several structures that fitted neutron scattering data equally well.

I. INTRODUCTION

The method of the rare earth (RE) spectroscopic probe has earlier been shown to complement substantially other methods of studying magnetic phase transitions (see, e.g., Ref. 1). The internal magnetic field that appears due to magnetic ordering in a system splits the Kramers doublets of a RE ion. The detection of an appropriate spectral line splitting versus temperature delivers information on a magnetic ordering in a system. Typically, the spectral resolution of grating spectrometers used for such studies is 0.5–1 cm^{-1} in the visible.[1] As we have shown recently,[2] inhomogeneous width of some RE spectral lines may be as small as 0.007 cm^{-1}. The most intense allowed in free ion optical transitions lie in the infrared and occupy broad spectral regions for a majority of RE^{3+} ions. It is advantageous to register such spectra by a Fourier transform spectrometer rather than by a classical one.[3]

In this paper, by the example of the RE–transition metal magnetic compounds related to high-T_c superconductors, we demonstrate that high resolution Fourier transform spectroscopy combined with some special technique proposed by us[4] broadens considerably the method of a RE spectroscopic probe and offers new possibilities in studying magnetic compounds. The work of the author's group is summarized.

II. SAMPLES AND EXPERIMENT

We have carried out the spectral studies of $R_2Cu_2O_5$[5,6] (here R stands for rare earth or yttrium), R_2BaCuO_5[8–12] and R_2BaNiO_5 (R=Lu,Yb)[13] magnetic cuprates and nickelates, which are related to high-T_c superconductors of the 123 type. It is interesting also to study these compounds in connection with the problem of low-dimensional magnetism. There are CuO planes in the structure of $R_2Cu_2O_5$ (R=Y,Tb–Lu,Sc,In), with intraplane Cu–Cu distances considerably smaller than interplane ones. The so-called "green phases" R_2BaCuO_5 (R=Y,Sm–Lu) and "brown phase" Nd_2BaCuO_5 of R–Ba–Cu–O superconducting ceramics contain isolated Cu^{2+} ions not interconnected by direct bonds through oxygen. Various Cu–O–O–Cu or Cu–O–R–O–Cu superexchange paths, low dimensional in particular, may dominate in these compounds, depending on a particular R^{3+} ion. R_2BaNiO_5 with R=Lu and Yb are isostructural to the green phases, while the other members of this family with R=Y, Nd–Gd, Dy–Tm (also studied by us[14,15]) have a completely different structure, containing isolated –Ni–O–Ni– chains.

Polycrystalline samples of the mentioned compounds, pure or with 1 at. % of erbium introduced as a spectral probe, were prepared from oxides by solid state reaction in air. The powder samples were carefully ground, mixed with ethanol, and put on the sapphire platelet directly before the window of the InSb detector. The whole assembly was inside an optical cryostat, either in liquid helium or in cold helium vapor. Near infrared spectra due to optical transitions in the intrinsic R^{3+} ion or Er^{3+} probe were registered at 2–120 K, with a spectral resolution down to 0.06 cm^{-1} employing the BOMEM DA3.002 Fourier transform spectrometer. In fact, we measured diffuse transmittance spectra. Absorption spectra were then calculated by the appropriate computer program. The width of some spectral lines in our samples at 2 K was as small as 0.1 cm^{-1}.

III. DETECTION OF MAGNETIC PHASE TRANSITIONS

High resolution spectrum of R^{3+} Kramers ion in a crystal is extremely sensitive to the changes of the local magnetic field at the place of this ion. This gives us a possibility to register unambiguously magnetic phase transitions, even those not detectable by other methods and, in some cases, to determine their nature. We have found, for the first time, magnetic ordering in Y_2BaCuO_5,[8] Lu_2BaCuO_5,[11] Nd_2BaCuO_5,[12] R_2BaNiO_5, with R=Lu, Nd, Sm, Eu, Dy, Ho, and Tm,[13–15] and specified the temperatures T_c of appropriate phase transitions. Spin reorientation first-order phase transitions not known before have been detected in Y_2BaCuO_5,[8,10] Dy_2BaCuO_5,[9] Lu_2BaCuO_5, and Yb_2BaCuO_5.[11]

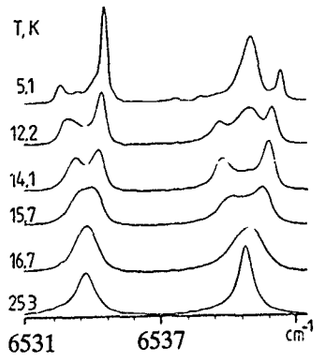

FIG. 1. Low-frequency part of the $^4I_{15/2} \rightarrow {}^4I_{13/2}$ absorption of the Er^{3+} probe in Y_2BaCuO_5 at different temperatures.

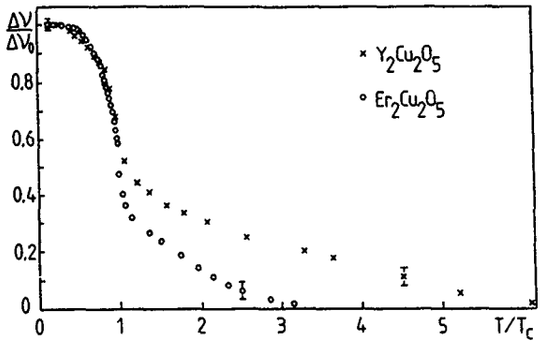

FIG. 2. Reduced splittings of the Er^{3+} probe spectral lines in $Y_2Cu_2O_5$ and $Er_2Cu_2O_5$.

On the other hand, our spectral method permits us to verify the interpretation of magnetic susceptibility (χ) and specific heat (c) measurements. Thus, we have shown that the maxima in $c(T)$ and $\chi(T)$ curves for Er_2BaCuO_5 and in the $\chi(T)$ curve for Er_2BaNiO_5, which had been attributed to phase transitions within the erbium magnetic subsystem, were, in fact, caused by the population changes within the ground Er^{3+} Kramers doublet split by an exchange interaction with an ordered d subsystem.[14,10]

IV. COEXISTENCE OF TWO DIFFERENT MAGNETIC PHASES

In the region of first-order spin reorientation phase transition, two magnetic phases coexist, usually, in a small interval of temperatures. The spectrum is a superposition of two different spectra with temperature-dependent relative intensities. High spectral resolution and precise temperature control ($\simeq$0.02 K) enabled us to separate these spectra and to register the temperature dependence of their intensities.[8–11]

We have found that in Y_2BaCuO_5 and Lu_2BaCuO_5, two different magnetic phases coexist in a broad range, starting from the temperature of spin reorientation transition T_R ($T_R \simeq 12$ K for Y_2BaCuO_5, $T_R \simeq 15$ K for Lu_2BaCuO_5), and down to the lowest measuring temperature of 2 K.[10,11] Evidently, various links Cu–O–O–Cu compete with each other in these compounds.

Figure 1, showing the lowest-frequency lines in the $^4I_{15/2} \rightarrow {}^4I_{13/2}$ spectral transition of the Er^{3+} probe in Y_2BaCuO_5 at different temperatures illustrates our research. The line splitting above 16.5 K manifests magnetic ordering of copper magnetic moments. At about 12.5 K, the spectrum changes abruptly. These changes are best seen for the high-frequency line in Fig. 1, namely, two components of the split line diminish in their intensity, while a new line appears between them. Such a behavior cannot be explained by population redistribution within the sublevels of the split Er^{3+} ground Kramers doublet, when changing the temperature. It clearly shows the appearance of a new magnetic phase with a different exchange field for the Er^{3+} probe. It is worth mentioning that neither magnetic susceptibility nor specific heat measurements suggested any magnetic phase transition in Y_2BaCuO_5.

V. SPECTRA OF Er^{3+} PROBE AND MAGNETIC STRUCTURE OF d SUBSYSTEM

We have shown that in the cuprates studied (1) the splittings of the Er^{3+} probe spectral lines are, mainly, due to the interaction with a d magnetic subsystem, while the interaction with f ions (RE ions) contributes little; (2) Er–Cu interactions are highly anisotropic. On these grounds, we proposed the method of the Er^{3+} probe in a series of isostructural f–d compounds to select the right magnetic structure of an ordered d subsystem from several structures that fitted neutron scattering data equally well. This method has been tested on $R_2Cu_2O_5$ cuprates,[6,7] where reliable neutron scattering data exist and applied to some of the R_2BaCuO_5 compounds.[11] The analogous work on the R_2BaNiO_5 chain nickelates is in progress now.

VI. LOW-DIMENSIONAL MAGNETIC CORRELATIONS AT $T > T_c$

For $T > T_c$ the splittings of spectral lines $\Delta\nu$ do not vanish—a "tail" is observed due to short range order. We have compared the dependences $\Delta\nu$ (T/T_c) for the Er^{3+} probe in two $R_2Cu_2O_5$ compounds with identical structure of copper magnetic moments μ_{Cu} (ferromagnetically ordered **ab** planes coupled antiferromagnetically with one another, μ_{Cu} aligned along the **b** axis), but with strongly different T_c temperatures, namely, in $Er_2Cu_2O_5$ ($T_c = 28$ K) and $Y_2Cu_2O_5$ ($T_c = 14$ K).[7,16] Figure 2 shows these dependences. Both dependences have a point of inflection at $T = T_c$, but the "tail" is about two times longer for the second one. This fact can be naturally explained if we assume that two-dimensional (2-D) magnetic correlations within isolated CuO planes take place below the same temperature in both compounds, while $Er_2Cu_2O_5$, where these planes interact through magnetic Er^{3+} ions orders three dimensionally at a two times higher temperature than $Y_2Cu_2O_5$ with nonmagnetic Y^{3+} ions.

We have observed in Nd_2BaCuO_5 an unusually long "tail" extending until about $10T_c$, and have explained it by quasi-1-D magnetism in this compound.[12] Such an explanation was confirmed later by the neutron scattering measurements.[17]

Various manifestations of low-dimensional magnetic correlations have been observed in the spectra of the erbium

probe in Ho_2BaCuO_5 and Er_2BaCuO_5,[10,16] Yb_2BaNiO_5, and Lu_2BaNiO_5.[13] Probably, the most interesting phenomenon is connected with different temperature behavior of the spectra from two different structural positions, Er1 and Er2 in these compounds. While the spectral lines of Er1 are markedly split only below T_c, those of Er2 demonstrate a long "tail" of residual splitting at $T \gg T_c$. We suppose that the Er2 ions are inside dominant magnetic chains and experience the establishment of short range order within a chain at $T \gg T_c$, while Er1 ions interconnect the chains and announce the 3-D ordering at T_c.

VII. SPLITTING OF MAGNETIC PHASE TRANSITION IN Dy_2BaCuO_5

Dy_2BaCuO_5 is a compound with well-separated temperatures for an ordering of d- and f-magnetic subsystems. While the magnetic subsystem of copper orders at $T_{N1}=20$ K, that of dysprosium—at $T_{N2}\simeq 11$ K. We have found[9] that the low temperature phase transition in Dy_2BaCuO_5 is split into two first-order transitions that follow one another with the interval of 0.2 K. Such a phenomenon may be caused by the interaction of critical fluctuations in a double $f-d$ system with a strongly different exchange for two subsystems.[18] To clarify the question, further experimental and theoretical work is necessary.

ACKNOWLEDGMENTS

The author would like to emphasize the decisive contribution of her collaborators, I. V Paukov, N. I. Agladze, Yu. A. Hadjiiskii, and G. G. Chepurko. The synthesis of the samples by B. V. Mill, Ja. Zoubkova, D. A. Kudrjavtsev, and E. P. Khlybov is greatly acknowledged.

How does mean-field theory work in magnetic multilayer systems?

Xiao Hu and Yoshiyuki Kawazoe
Institute for Materials Research, Tohoku University, 2-1-1 Katahira, Aoba-ku, Sendai 980, Japan

Phase transition and critical phenomena in magnetic multilayer systems are studied in terms of Ginzburg–Landau mean-field theory. Detailed calculations are carried out for a system consisting of a layer of finite thickness coupled to a semi-infinite bulk magnet. Correlation functions are derived and the shift in critical point with the overlayer thickness and coupling between the neighboring layer is evaluated. A new critical exponent $\tilde{\nu}=1$ is derived for the divergence of the effective extrapolation length at the interface with temperature and/or layer thickness.

I. INTRODUCTION

Magnetic multilayers are known to be very useful for magneto-optical recording.[1,2] The state-of-the-art technologies are so sophisticated as to resort to the difference among the critical points in the individual layers and the detailed temperature dependences of magnetization and anisotropy. Among the problems that have been raised from the experimental side in the recent years, we would like to call the attention to the shift of the critical point and new critical phenomena in magnetic multilayer structures coming from the finite thicknesses of the individual layers. For example, in the bilayer system for the magneto-optical recording, the thickness of the layer with in-plane anisotropy is typically of order of 100 Å.[2] Therefore, the thin layer can neither be treated simply as the surface to the bulk medium, nor be approximated as a semi-infinite bulk, both of which have been studied extensively.[3–8] One has to treat a system consisting of a layer with finite thickness coupled to a semi-infinite bulk.[9–12]

Since this structure is the simplest one that exhibits the most important aspects of multilayer structures, we concentrate on it in the present study. The geometry of the system is schematically shown in Fig. 1. The magnetic constants are taken to be uniform in the individual subsystems and to change abruptly at the interface.

II. FORMALISM AND RESULTS

The Ginzburg–Landau free-energy functional[3] for the present system under an external field can be given as

$$\frac{F}{T}=\int d\mathbf{x}_{\parallel}\int_0^L\left[\frac{1}{2}A_1m^2+\frac{1}{4}B_1m^4-H_{\mathrm{ext}}m+\frac{1}{2}C_1\left(\frac{\partial m}{\partial z}\right)^2\right]dz+\int d\mathbf{x}_{\parallel}\frac{1}{2}C_1\lambda^{-1}m^2(z=L)+\int d\mathbf{x}_{\parallel}\int_{-\infty}^0\left[\frac{1}{2}A_2m^2+\frac{1}{4}B_2m^4-H_{\mathrm{ext}}m+\frac{1}{2}C_2\left(\frac{\partial m}{\partial z}\right)^2\right]dz, \tag{1}$$

with the following interface condition:

$$m(\mathbf{x}_{\parallel},z=+0)=m(\mathbf{x}_{\parallel},z=-0). \tag{2}$$

The thickness L will be kept finite but large on the scale of the atomic lengths. The areas of the surfaces and the interface, on the other hand, are taken to be infinite. The coefficients of the quadratic terms are given by

$$A_1=A_1'(T-T_{c1}),\qquad A_2=A_2'(T-T_{c2}), \tag{3}$$

where T_{c1} and T_{c2} are the mean-field critical points for the layer in the infinite-thickness limit and the semi-infinite bulk, respectively, and A_1' and A_2' are positive constants. The coefficients B_i and C_i for $i=1$ and 2 are taken to be positive with weak temperature dependences. The parameter λ is adopted to describe the surface condition of the thin layer. In the present paper, we consider the case of $T_{c1}>T_{c2}$ and $\lambda>0$. The free-energy functional studied up to the present[4–6] can be obtained, putting $L=0$ in (1).

The differential equations for the correlation functions are derived from (1) and (2) as

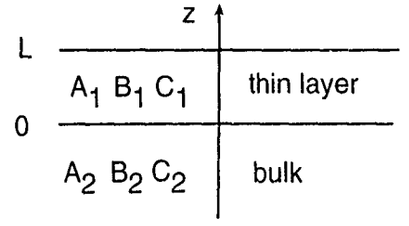

FIG. 1. Geometry of the present system: a thin layer coupled to a semi-infinite bulk.

$$\begin{cases} -\dfrac{\partial^2 S(\mathbf{Q}_\parallel;z,z')}{\partial z^2}+\gamma_1^2 S(\mathbf{Q}_\parallel;z,z')=\dfrac{1}{C_1}\,\delta(z-z'), & 0<z<L, \\ -\dfrac{\partial^2 S(\mathbf{Q}_\parallel;z,z')}{\partial z^2}+\gamma_2^2 S(\mathbf{Q}_\parallel;z,z')=0, & z<0, \end{cases} \tag{4}$$

for $z'>0$, and

$$\begin{cases} -\dfrac{\partial^2 S(\mathbf{Q}_\parallel;z,z')}{\partial z^2}+\gamma_1^2 S(\mathbf{Q}_\parallel;z,z')=0, & 0<z<L, \\ -\dfrac{\partial^2 S(\mathbf{Q}_\parallel;z,z')}{\partial z^2}+\gamma_2^2 S(\mathbf{Q}_\parallel;z,z')=\dfrac{1}{C_2}\,\delta(z-z'), & z<0, \end{cases} \tag{5}$$

for $z'<0$, where

$$S(\mathbf{r},\mathbf{r}')=\int \frac{d\mathbf{Q}_\parallel}{(2\pi)^{d-1}} S(\mathbf{Q}_\parallel;z,z')\exp[i\mathbf{Q}_\parallel\cdot(\mathbf{x}_\parallel-\mathbf{x}'_\parallel)], \tag{6}$$

$$\gamma_1^2\equiv\xi_1^{-2}+Q_\parallel^2\equiv\frac{A_1}{C_1}+Q_\parallel^2, \quad \gamma_2^2\equiv\xi_2^{-2}+Q_\parallel^2\equiv\frac{A_2}{C_2}+Q_\parallel^2. \tag{7}$$

The boundary conditions are

$$\begin{aligned} &\left.\frac{\partial S(\mathbf{Q}_\parallel;z,z')}{\partial z}\right|_{z=L}=-\lambda^{-1}S(\mathbf{Q}_\parallel;z,z')|_{z=L}, \quad \left.\frac{\partial S(\mathbf{Q}_\parallel;z,z')}{\partial z}\right|_{z=-\infty}=0, \\ &S(\mathbf{Q}_\parallel;z,z')|_{z=+0}=S(\mathbf{Q}_\parallel;z,z')|_{z=-0}, \quad \left.\frac{\partial S(\mathbf{Q}_\parallel;z,z')}{\partial z}\right|_{z=+0}=\left.\frac{\partial S(\mathbf{Q}_\parallel;z,z')}{\partial z}\right|_{z=-0}. \end{aligned} \tag{8}$$

It is not difficult to obtain the solutions to the above equations, and the correlation function is given explicitly for (4),

$$\begin{aligned} S(\mathbf{Q}_\parallel;z,z')=&\frac{1}{2C_1\gamma_1}\frac{(C_1\gamma_1-C_2\gamma_2)\exp(-\gamma_1 z)+(C_1\gamma_1+C_2\gamma_2)\exp(\gamma_1 z)}{(C_1\gamma_1+C_2\gamma_2)(\gamma_1+\lambda^{-1})/(\gamma_1-\lambda^{-1})-(C_1\gamma_1-C_2\gamma_2)\exp(-2\gamma_1 L)} \\ &\times\left\{\exp[-\gamma_1(2L-z')]+\frac{\gamma_1+\lambda^{-1}}{\gamma_1-\lambda^{-1}}\exp(-\gamma_1 z')\right\}, \end{aligned} \tag{9}$$

for $0\leq z, z'\leq L$.

At first glance, the above correlation function in the layer becomes singular at the critical point T_{c1}. One finds, however,

$$\begin{aligned} &\frac{1}{2\gamma_1}\frac{(C_1\gamma_1-C_2\gamma_2)\exp[-\gamma_1(2L+z-z')]}{(C_1\gamma_1+C_2\gamma_2)(\gamma_1+\lambda^{-1})/(\gamma_1-\lambda^{-1})-(C_1\gamma_1-C_2\gamma_2)\exp(-2\gamma_1 L)} \\ &=\int_{-\infty}^{\infty}\frac{dk}{2\pi}\frac{-\exp[ik(L+z-z')+i\theta_1+i\theta_2]}{(k^2+\gamma_1^2)2i\,\sin(kL+\theta_1+\theta_2)}+\frac{1}{2}\sum_{n=1,2,..}\frac{\cos[k_n(z-z')]}{L+d\theta_1/dk+d\theta_2/dk}\times\frac{1}{k_n^2+\gamma_1^2}, \end{aligned} \tag{10}$$

and three other similar relations, where the summation is on the solutions of the following equation:

$$kL+\tan^{-1}\frac{k}{C_2'\gamma_2}+\tan^{-1}k\lambda=n\pi, \quad \text{for } n=1,2,..., \tag{11}$$

graphically solved in Fig. 2, $\theta_1=\tan^{-1}(k/C_2'\gamma_2)$ and $\theta_2=\tan^{-1}(\lambda k)$. The integral terms, which show singularities at T_{c1}, cancel completely with each other, and thus the correlation function $S(\mathbf{Q}_\parallel;z,z')$ in (9) is equivalent to

$$\begin{aligned} &S(\mathbf{Q}_\parallel;z,z') \\ &=\frac{1}{C_1}\sum_{n=1,2,}\frac{\cos[k_n(z-z')]-\cos[k_n(z+z')+2\theta_1]}{L+d\theta_1/dk+d\theta_2/dk} \\ &\quad\times\frac{1}{k_n^2+\gamma_1^2} \\ &=\frac{1}{C_1}\sum_{n=1,2,}\frac{\sin(k_n z+\theta_1)\sin(k_n z'+\theta_1)}{L+d\theta_1/dk+d\theta_2/dk}\times\frac{1}{k_n^2+\gamma_1^2}. \end{aligned} \tag{12}$$

The above complete cancellation among the integral terms is the mechanism responsible for the shift of critical point in the layer of finite thickness.

The correlation function in real space is then given as

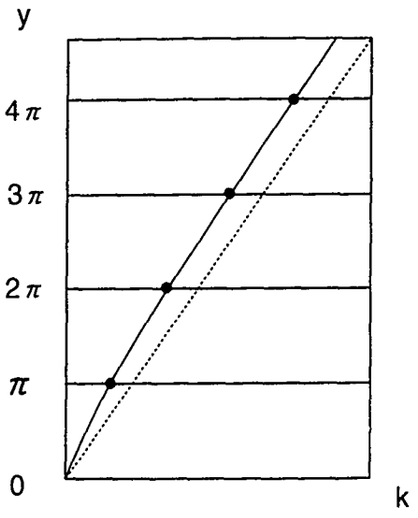

FIG. 2. Graphical solutions for (11): Solid curves are from (11); the dashed line is for $y=kL$.

$$S(\mathbf{r},\mathbf{r}')=\frac{2}{C_1}\sum_{n=1,2,\ldots}\frac{\sin(k_n z+\theta_1)\sin(k_n z'+\theta_1)}{L+d\theta_1/dk+d\theta_2/dk}\times G_{d-1}(\mathbf{x}_\parallel-\mathbf{x}'_\parallel,k_n^2+\xi_1^{-2}), \tag{13}$$

where the function $G_d(\mathbf{r},t)$ is defined in Ref. 6. The critical point is determined by $k_1^2+\xi_1^{-2}=0$ from (13). As $k_1^2>0$, it is now clear that $T_c<T_{c1}$.

Incorporating the definitions of the correlation lengths ξ_1 and ξ_2 in (7), one arrives at the following equation for the critical point T_c:

$$L\sqrt{\frac{-A_1}{C_1}}=\cot^{-1}\sqrt{\frac{-A_1C_1}{A_2C_2}}+\cot^{-1}\lambda\sqrt{\frac{-A_1}{C_1}}. \tag{14}$$

Comparing with (12) in Ref. 8, it becomes clear that the first term on the right-hand side in the above equation expresses the effect of interfacial coupling. Therefore, the shift of critical point of a layer depends on the magnetic properties of the neighboring layer to which it is coupled in a fashion given in the above relation. The critical point T_c is also the temperature at which spontaneous magnetic ordering occurs in the thin layer. We note that this coincidence is not trivial in the present inhomogeneous system.

As $L\to\infty$, the minimal pole k_1 approaches zero and the critical point is then restored to T_{c1}, as it should be by definition.

As for the correlation function within the semi-infinite bulk, it is found that the effect from the thin layer to the semi-infinite bulk can be expressed effectively by an extrapolation length $\xi_{\perp,e}$. The effective extrapolation length at the interface in the present system shows a clear temperature dependence, forming a contrast to the ones in previous studies[4–6] and that on the top surface of the present structure. Furthermore, it diverges with a new exponent $\tilde{\nu}$,

$$\xi_{\perp,2}\sim|1-T/T_*|^{-\tilde{\nu}},\quad T\to T_*, \tag{15}$$

with $\tilde{\nu}=1$, where $T_*<T_{c1}$ is given by

$$L\sqrt{A_1'(T_{c1}-T_*)/C_1}=\cot^{-1}\lambda\sqrt{A_1'(T_{c1}-T_*)/C_1}. \tag{16}$$

This critical exponent should be compared with the well-known $\nu=\frac{1}{2}$ for the correlation length.

The divergence of the effective extrapolation length can also be observed as the thickness of the layer increases, while the temperature is fixed. The critical exponent is also $\tilde{\nu}=1$ in the present mean-field theory.

It can be shown, within the present approach, that as the thickness L of the layer approaches infinity, the effective extrapolation length becomes $C_2\xi_1/C_1$. It diverges at $T=T_{c1}$ with the critical exponent $\nu=\frac{1}{2}$ for the correlation length. Therefore, the divergence of the interfacial extrapolation length with the exponent $\tilde{\nu}=1$ is a characteristic phenomenon in systems where a layer with finite thickness is coupled into the structure, such as the one discussed in the present paper.

III. SUMMARY

Magnetic multilayer structures are studied within the Ginzburg–Landau free-energy functional formalism. The shift of critical point is discussed, and the effects from the finiteness of layer thickness and from the coupling between neighboring layers are clarified for a system consisting of a magnetic overlayer on a bulk ferromagnet. The present result is expected to be important for the practical multilayer-disk design.

Magnetic properties of the one-dimensional Heisenberg compounds (3-X-anilinium)$_8$[CuCl$_6$]Cl$_4$; X=Br, I

Gayatri Vyas and Leonard W. ter Haar[a)]
Department of Chemistry, University of Texas, El Paso, Texas 79968-0513

Recent x-ray diffraction studies have suggested that (3-Cl-anilinium)$_8$[CuCl$_6$]Cl$_4$ exhibits *compressed* [CuCl$_6$]$^{4-}$ octahedra. We report here the synthesis of the (3-Br-anilinium)$_8$[CuCl$_6$]Cl$_4$ and (3-I-anilinium)$_8$[CuCl$_6$]Cl$_4$ analogs. Their magnetic behavior is quite similar to one another, and in comparison to the *chloro* compound, the only similarity is that they all exhibit chain magnetism, as evidenced by their broad maxima in the region of 9–12 K. The *bromo* and *iodo* compounds do not exhibit the field dependence of the *chloro* compound, and in this respect, the *chloro* compound remains unique. For all three compounds, magnetic susceptibility data can be analyzed by the antiferromagnetic one-dimensional Heisenberg model.

I. INTRODUCTION

Bright yellow needle-like crystals with the composition (3-chloro-anilinium)$_8$CuCl$_{10}$ were first reported to consist of discrete [CuCl$_6$]$^{4-}$ ions in a tetragonal compressed octahedral coordination geometry.[1] We subsequently reported an independent x-ray structure determination at 298 K that reproduced this apparent compression, and provided structure determinations at 150 and 110 K, carried out in two independent laboratories, that revealed no significant changes concerning the compression versus elongation dilemma.[2] To date, all crystal structure determinations (293–110 K) have revealed a tetragonally *compressed* octahedron with four long Cu–Cl bonds of intermediate length (2.6 Å) and two short Cu–Cl bonds of 2.28 Å. The [CuCl$_6$]$^{4-}$ ions form a linear chain through axial Cl–Cl contacts (3.99 Å) between the [CuCl$_6$]$^{4-}$ ions, with the axis of tetragonal compression parallel to the axis of chain propagation.

In addition to the low-temperature structure determinations, we demonstrated with low-temperature (down to 1.7 K) single crystal magnetic susceptibility and EPR data that the material revealed a complex magnetic problem with several key questions concerning Jahn–Teller related lattice dynamics and disorder.[2] More recently, low-temperature electronic spectral data have been invoked in conjunction with the magnetic and EPR data to suggest that at the local level, each [CuCl$_6$]$^{4-}$ ion is tetragonally *elongated*, and that the axis of elongation is "antiferrodistortively" disordered over two possible sites, thereby leading to the crystallographically determined bond lengths that correspond to intermediate long bonds averaged over the unit cell and suggestive of *compressed* geometry.[3] These possibilities have stimulated additional synthetic, theoretical, spectroscopic, magnetic, and EPR studies. In this paper, we report the synthesis and magnetic characterization of (3-bromo-anilinium)$_8$CuCl$_{10}$ and (3-iodoanilinium)$_8$CuCl$_{10}$.

II. EXPERIMENT

(3-Br-anilinium)$_8$CuCl$_{10}$ and (3-I-anilinium)$_8$CuCl$_{10}$ were prepared by stoichiometric reaction of the appropriate 3-X-aniline with CuCl$_2$·2H$_2$O in saturated 60/40 HCl/ethanol solutions. Second crops of crystals typically yielded higher quality product. Both products are bright yellow needle-like crystals. Elemental analysis, Atlantic Microlab: C$_{48}$H$_{56}$Cl$_{10}$Br$_8$N$_8$Cu, expected (actual) H 3.13 (3.08), C 31.99 (31.99), N 6.22 (6.21), Cl 19.67 (19.63), Br 35.47 (35.42); C$_{48}$H$_{56}$Cl$_{10}$I$_8$N$_8$Cu, expected (actual) H 2.59 (2.52), C 26.47 (26.51), N 5.14 (5.11), Cl 16.28 (16.30), I 46.61 (46.30).

All attempts to perform a single crystal x-ray structure determination have so far been unsuccessful. The habit of the acicular crystals is that of bundled fibers, thereby rendering most crystals as too small for diffraction, or too fragile with respect to cleavage when trying to cut the larger crystals to size. X-ray powder diffraction has been utilized to characterize the materials for comparison to the chloro derivative. Data were collected on a Rigaku D2000 and a Scintag XDS2000 at 293 K. Powder spectra for the bromo and iodo derivatives were superimposable and were fit to a tetragonal cell: (3-Br-anilinium)$_8$CuCl$_{10}$, $a=8.92$ Å, $c=11.38$ Å; (3-I-anilinium)$_8$CuCl$_{10}$, $a=8.92$ Å, $c=11.38$ Å.

Magnetic susceptibility measurements on freshly prepared powder samples were collected in the temperature range 1.7–300 K using a Quantum Design SQUID-based magnetometer utilizing modifications and procedures described elsewhere.[4] Data were corrected for temperature independent magnetism (X=Br: -1012×10^{-6} emu/mol; and X=I: -1124×10^{-6} emu/mol) using Pascal's constants for the diamagnetic components[5] and a T.I.P. per Cu(II) ion of 60×10^{-6} emu/mole. Figures in this paper are based on the molecular weights of 1802.3 g/mol (Br) and 2178.3 g/mol (I).

III. RESULTS AND DISCUSSION

All of the crystal structure determinations[1,2] of (3-Cl-anilinium)$_8$[CuCl$_6$]Cl$_4$ have indicated that discrete 3-chloroanilinium ions, uncoordinated chloride ions, and [CuCl$_6$]$^{4-}$ ions comprise the triclinic unit cell. The [CuCl$_6$]$^{4-}$ ions are linked into a quasilinear chain by way of axial Cl–Cl interactions; this lattice arrangement leads to the characteristic chain magnetism that has now been repeatedly verified.[1–3] Since we have only been able to collect powder diffraction data for the bromo and iodo derivatives, the notable observation is that the powder diffraction pattern of the

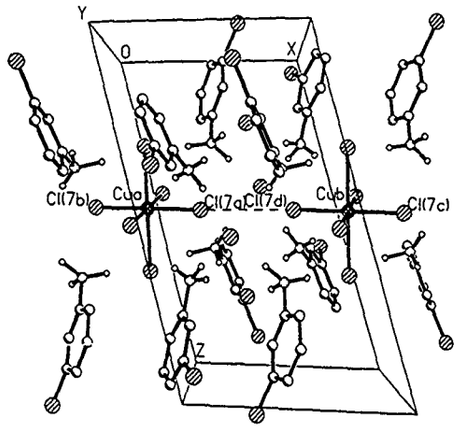

FIG. 1. View perpendicular to the chain structure in (3-X-anilinium)$_8$[$CuCl_6$]Cl_4; the superexchange pathway is the Cu–Cl···Cu–Cl contact.

chloro derivative (triclinic) is noticeably more complex than the diffraction patterns of the bromo and iodo derivatives (which are superimposable on one another within experimental error). In view of the elemental analyses, which confirm that the molecular composition of all three compounds corresponds to the general formula (3-X-anilinium)$_8$[$CuCl_6$]Cl_4, the tetragonal unit cell parameters for the bromo and iodo derivatives equate to a smaller unit cell with a smaller volume and a higher symmetry.

On this basis, the general packing arrangement of the $[CuCl_6]^{4-}$ ions in the bromo and iodo derivatives is expected to be similar to the chloro compound, i.e., a quasilinear chain arrangement similar to the chain structure of (3-Cl-anilinium)$_8$[$CuCl_6$]Cl_4, shown in Figs. 1 and 2. The copper–copper separation along the chain is 8.55 Å in the chloro compound. Antiferromagnetic superexchange interactions along such a chain arise from the –Cl(7′)–Cu–Cl(7)–Cl(7′)–Cu–Cl(7)–pathway, where the only close contact from an axial Cl(7) is to another axial Cl(7′) on a neighboring complex along the chain direction. This contact has been shown to be temperature dependent [3.995 (293 K)/3.805 (110 K)], as a result of thermal contraction of the unit

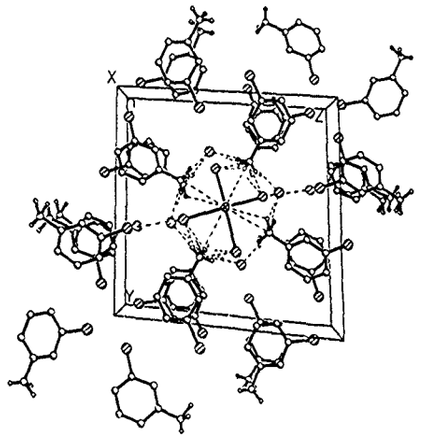

FIG. 2 Packing view along the chain axis in (3-X-anilinium)$_8$[$CuCl_6$]Cl_4.

cell,[2] and could very well lead to a temperature-dependent Heisenberg exchange. This distance is slightly greater than the van der Waal's contact of 3.60 Å.[6] The next closest contacts for the axial chlorides are to the uncoordinated chlorides at over 4.0 Å.

Since the structure of the $[CuCl_6]^{4-}$ ion may be a time-averaged structure in which the four "long" equatorial Cu–Cl bonds (of intermediate length, 2.6 Å) are actually an average of two long Cu–Cl bonds of 2.9 Å and two short bonds of 2.3 Å; then the crowded equatorial-coordinated-chloride to organo-chloro distance of 3.45 Å may be easily affected by chemical modification of the aniline metasubstituent. With the bromo and iodo derivatives, we have effected such a change. With the larger organo-halogens, the overall structure has clearly adjusted in order to accommodate the larger atoms. Given that the general nature of the lattice packing is preserved, the tetragonal a axis (8.92 Å) for both the bromo and iodo derivatives may reflect a Cu–Cu separation along the chain axis that is increased, relative to the 8.55 Å of the chloro compound. Precisely how the larger organo-halogens result in a structure of higher symmetry must await a complete structure determination.

The magnetic susceptibility data provide the strongest evidence that the quasichain structure in (3-Cl-anilinium)$_8$[$CuCl_6$]Cl_4 is also present in the bromo and iodo compounds. SQUID-based temperature-dependent magnetic susceptibility data were collected for the bromo and iodo derivatives, with applied magnetic fields in the range 0.1 mT to 1.0 T, and in the temperature range 1.7–300 K. Representative data for the bromo derivative are plotted in Fig. 3 as χ_m, $1/\chi_m$, and $\mu_{\text{eff}}=2.828(\chi_m T)^{1/2}$; the iodo data are nearly identical. Several dominant features are noteworthy. The χ_m of the bromo material exhibits a susceptibility maximum at a temperature of 11.5 K (iodo: 10.5 K) and μ_{eff} drops from near 1.8 B.M. at 300 K toward 0.4 B.M. near 2 K. These data are in qualitative agreement with the previous susceptibility studies on the chloro compound and suggest the presence of antiferromagnetic exchange interactions in a one-dimensional magnetic system.

In view of the observation that a quasichain structure is maintained for the bromo and iodo derivatives, it is reasonable to fit the susceptibility data to the uniform $S=\frac{1}{2}$ Heisenberg spin chain, given by the Hamiltonian

$$H=-2J_{ij}\sum_{i<j}\mathbf{S}_i\cdot\mathbf{S}_j,$$

where J_{ij} is the isotropic intrachain exchange parameter. The theoretical treatment of such a uniform chain was first provided by Bonner and Fisher.[7] Hall[8] later provided a useful analytical expression for the temperature dependence of the magnetic susceptibility as

$$\chi_{\text{BF}}=(Ng^2\mu_B^2/k_BT)[A+Bx+Cx^2]/[1+Dx+Ex^2+Fx^3], \quad (1)$$

where the coefficients[8] are given as $A=0.25$, $B=0.149\,95$, $C=0.300\,94$, $D=1.9862$, $E=0.688\,54$, $F=6.0626$, and $x=|J|/k_BT$; N is Avogadro's number, μ is the Bohr magneton, k is the Boltzmann constant, and g is the gyromag-

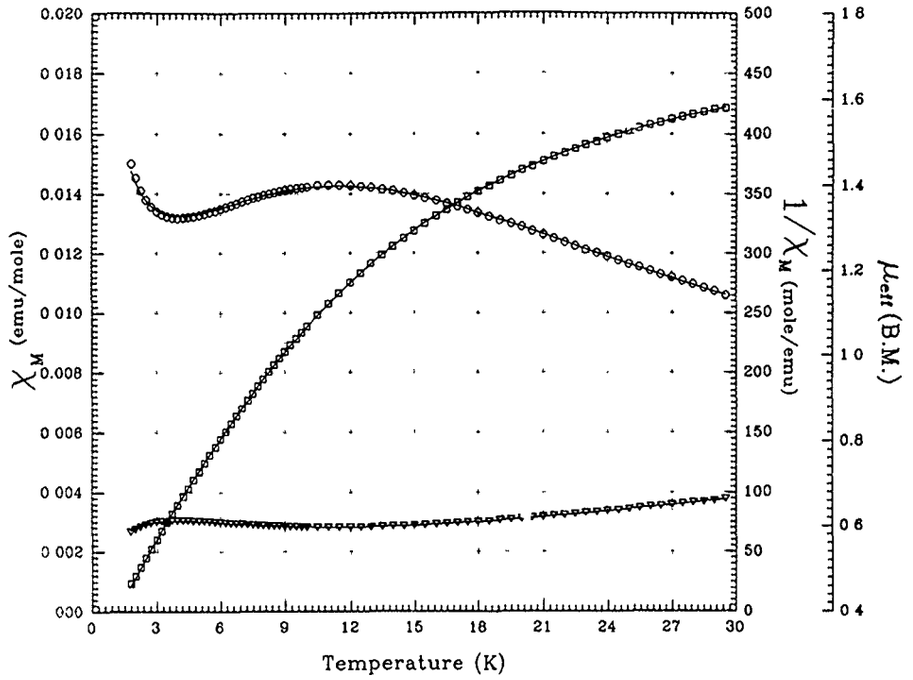

FIG. 3 Magnetic data for (3-Br-anilinium)$_8$[CuCl$_6$]Cl$_4$, curves are drawn using the best-fit parameters given in the text (○—χ_m, ▽—$1/\chi_m$, □—μ_{eff}).

netic ratio for the electron. Interchain interactions, denoted zJ', can be accounted for by applying a molecular field correction to the χ_{BF} expression, thus obtaining

$$\chi_{corr}=\chi_{BF}/(1-2zJ'\chi_{BF}/Ng^2\mu_B^2), \quad (2)$$

where J' is the interchain exchange parameter and z is the number of nearest neighbors. A best fit of the χ_{corr} expression to the χ_m data using nonlinear regression[9] yielded best-fit fitting parameters for *bromo*: $J=-6.9$ cm^{-1}, $zJ'=-1.64$ cm^{-1}, % impurity=0.20 and $g=2.13$; and for *iodo*: $J=-6.6$ cm^{-1}, $zJ'=-1.35$ cm^{-1}, % impurity=0.26 and $g=2.13$. The impurity fitting parameter was obtained by adding a monomeric Curie term to Eq. (2); this helps to account for the Curie tail evident in the data.

The solid line in Fig. 3 is generated with the best-fit parameters; it is in excellent agreement with the temperature dependence and the position of the maximum, as calculated according to the Bonner–Fisher model ($k_BT_{max}/|J|=1.2828$). The best-fit values for g are in excellent agreement with the EPR g value of 2.14. Unlike the chloro compound, the bromo and iodo derivatives do not exhibit magnetic field dependence below 10 K. They do, however, always exhibit the impurity tail clearly seen in Fig. 3. Several sample preparations have been used to demonstrate that the tail is essentially independent of the sample preparation technique or crystal quality. It has often been surmised that such effects can then be ascribed to finite chain effects because short finite chains with an odd number of spins would have a diverging susceptibility at low temperatures. It is clear however, that the magnitude of the bromo and iodo exchange energies are less than the -9.3 cm^{-1} found for the *chloro* compound, with that of the iodo material being slightly less than that of the bromo material. The decrease in the magnitude of the exchange energy corresponds well with the expected increased distance of the Cu–Cl···Cl–Cu superexchange pathway, given that the larger organo-halogens increase this distance, as suggested by the powder diffraction data. Single crystal studies continue to be addressed.

Comparison of two-dimensional Heisenberg and two-dimensional *XY* model behaviors in Pd(1.2 at. % Fe) films

J. D. McKinley
Physics Department and Rice Quantum Institute, Rice University, Houston, Texas 77251-1892

Multilayer Pd/Pd(1.2 at. % Fe)/Pd thin films were prepared by dc magnetron sputtering and characterized with dc SQUID magnetometry. Evidence for two-dimensional (2D) Heisenberg and 2D *XY* model behaviors was found in two different regions of temperature. In these temperature regimes, our data agree with the predicted form for magnetization M and susceptibility χ as functions of field and temperature. Both model's susceptibilities were found to fit our data. M and χ exhibit discontinuities at magnetic layer thickness-dependent temperatures which separate the different model behaviors.

I. INTRODUCTION

The Pd/Pd(1.2 at. % Fe)/Pd random quenched thin film trilayers were originally prepared as a model system for studying two-dimensional Heisenberg (2DH) model magnetism in a single magnetic layer.[1,2] We were motivated by previous studies of bulk dilute Fe-doped Pd alloys[3,4] showing Fe concentrations in Pd above 0.1 at. % to be 3D Heisenberg ferromagnets; dimensional reduction should result in two-dimensional behavior. Thick Pd layers provide good crystal growth, prevent oxidation in the Pd(Fe) layer, and ensure "bulk" lattice constants in the magnetic layer. The Pd(Fe) magnetic layer thickness L was varied over the range 5 Å$<L<$500 Å. Polycrystalline Pd(300 Å)/Pd(Fe) (L Å)/Pd(300 Å) films were grown on Si(111) substrates at room temperature using dc magnetron sputtering, at rates of ~1 Å/s in a UHV chamber in pressures $P\leqslant 5\times10^{-9}$ Torr. The films were characterized in a parallel applied field using a dc SQUID magnetometer. The 2DH model magnetic behaviors were observed in each film over a range of temperatures below the bulk Pd(Fe) $T_c\approx 40$ K.

The magnetic properties in the Pd(Fe) films indicate a phase transition or crossover to a different model behavior, possibly 2D *XY*,[1] at a thickness-dependent temperature. This behavior persists to an even lower temperature, where finite magnetizations and hysteresis loops are observed. We also observed peaks in the low-field magnetization versus temperature dependence.

It is well known[5] that there is no long-range ferromagnetic order in a fully isotropic 2DH ferromagnet. Real physical systems have anisotropies, which are often temperature dependent. The Pd(Fe) layer has a slightly smaller lattice constant[4] than the pure Pd layers, and this produces in-plane anisotropy.

The dimensional reduction of the Pd(Fe) layer also results in finite size[2] effects. At some temperature the percolating magnetic cluster in the Pd(Fe) layer reaches the finite thickness of the magnetic layer, constraining it to grow laterally at lower temperatures. Other finite sizes possibly affecting magnetic percolation are the crystallites from 100 to 300 Å in size, closely packed into islands with 0.1- to 0.2-μm lateral diameters, as determined from x-ray crystallography and transmission electron microscopy.

Finite field magnetization $M(H)$ data and susceptibility $\chi(T)$ data are presented for a 500-Å-thick Pd(Fe) layer film. Model predictions for 2DH and 2D *XY* behaviors are compared to these data in two separate regions of temperature.

II. 2D HEISENBERG AND 2D *XY* MODEL BEHAVIORS

The 2D Heisenberg and 2D *XY* models predict[6–10] similar field dependence of the magnetization and temperature dependence of the susceptibility, as shown below:

$$\chi_{2DH}(T)\sim\exp(B/T),\quad M_{2DH}(H)\sim A(T)\ln(H/H^*),$$

$$\chi_{2D\ XY}(\tau)\sim\exp(B'/\tau),\quad M_{2D\ XY}(H)\sim H^{1/\delta},\quad \delta=15,$$

where H is the externally applied field, H^* is a thickness-dependent constant, T the ambient temperature, and $\tau=(T-T_{KT})/T_{KT}$ is the reduced temperature using the Kosterlitz–Thouless temperature as the Curie temperature. The prefactor $A(T)$ is a function[7] of temperature T, and exponents B and B' depend on the magnetic layer thickness. Because the susceptibility model predictions are similar, the different model behaviors must be carefully distinguished. Physical reasons are given for interpreting the low- and high-temperature regions as corresponding to 2D *XY* (see below) and 2DH[1] behaviors, respectively. Interestingly, the 2D *XY* prediction for equation of state critical exponent $\delta=15$ is the same as for the 2D Ising model.

III. RESULTS AND DISCUSSION

In Figs. 1(a) and 1(b), the susceptibility data are fit to the 2DH and 2D *XY* predictions, respectively. Both models fit the whole range of data. In Fig. 1(a), the 2DH model $\chi_{2DH}(T)$ is plotted as $\ln(\chi)$ vs $1/T$. The high- and low-temperature regions are divided by a fairly sharp "kink" in the curve, as indicated by the lines drawn onto the data. The lines themselves are not the fits to the data, but separate fits to each region show that both portions are very linear, with correlation coefficients $R\sim0.999$. A line drawn from the intersection of the extrapolated fits indicates a kink temperature $T_{kink}\cong 36$ K. The 2D *XY* model $\chi_{2D\ XY}(\tau)$ is fitted to the data as $\ln(\chi)$ vs $\tau^{-1/2}$ in Fig. 1(b). Remarkably, for the 500-Å Pd(Fe) film data a single line can fit the susceptibility over the full range of temperatures. Two regions in the data can be determined with slightly different slopes, as the drawn lines indicate, but the differences are within uncertainties.

Magnetization data for the 500-Å-thick Pd(Fe) film is fitted to the 2DH model in Fig. 2(a) and to the 2D *XY* model

 0021-8979/94/76(10)/7114/3/$6.00 © 1994 American Institute of Physics

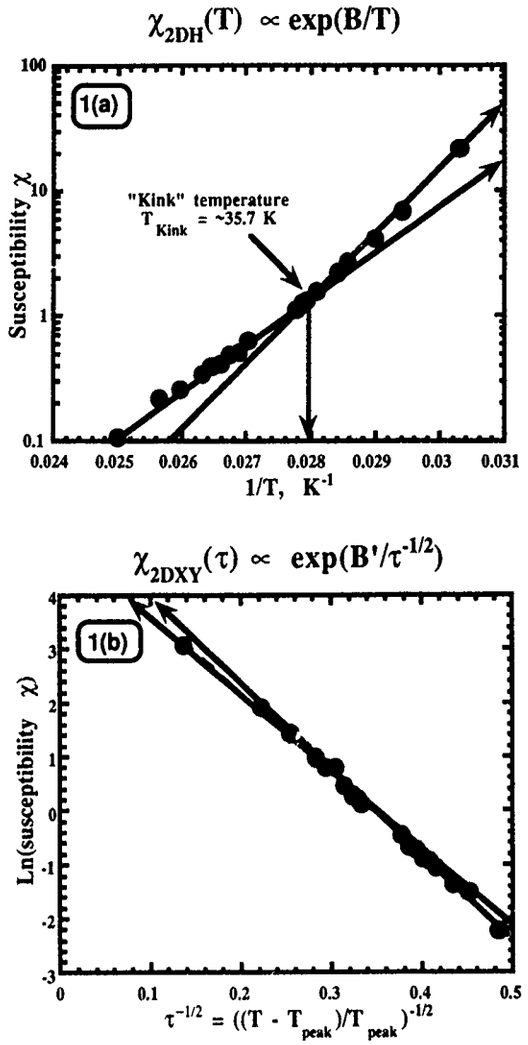

FIG. 1. Susceptibility χ vs temperature T plots for a 500-Å-thick Pd(Fe) magnetic layer. Plots (a) and (b), respectively, assume 2DH and 2D XY model behavior over the full range of temperatures from T_c [bulk Pd(Fe)] ≈40 K down to T_{peak}(500 Å)=32.4±0.2 K. Both linear regions in (a) fit the 2DH prediction well, with the slope merely increasing ~50% at the "kink" temperature T_{kink}≈36 K. The 2D XY assumption in plot (b) fits the entire temperature region; a slight change in slope near T_{kink} lies within the uncertainty of the 500-Å film data. The changes in the slope at T_{kink} are a function of magnetic layer thickness.

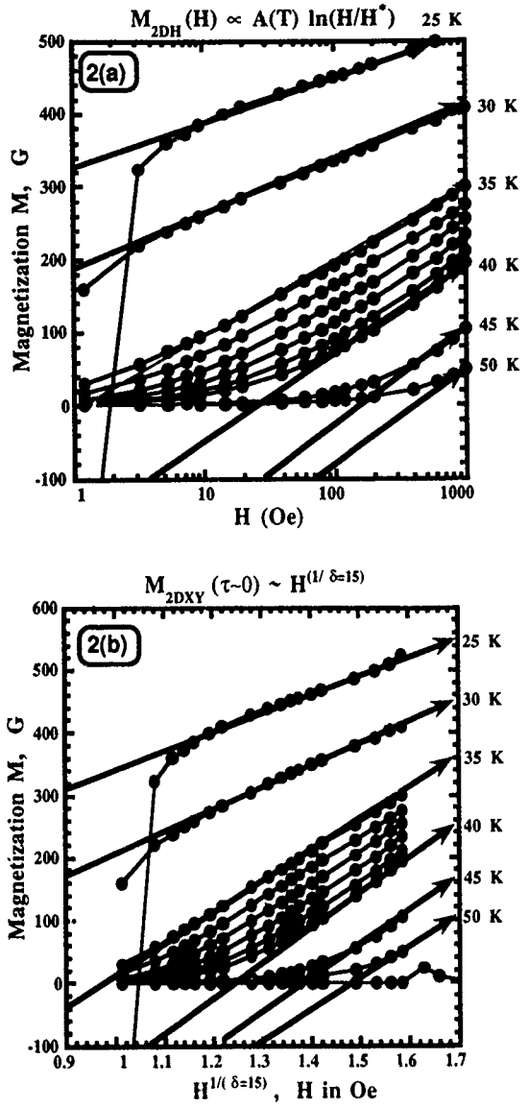

FIG. 2. Magnetization M vs applied field H plots for a 500-Å-thick Pd(Fe) magnetic layer. Plot (a) over temperatures $32.4 \leq T \leq 40.0$ K yields good agreement with 2DH behavior at finite fields. Plot (b) assuming 2D XY behavior indicates the onset of 2D XY behavior near T_{kink}≈36 K. Both model behaviors can be said to fit the data, but each seems to fit one temperature region slightly better

in Fig. 2(b). Here, differences between the two models are more apparent. The data were originally taken to study the 2DH behavior at higher temperatures, but enough data at lower temperatures was taken for a useful comparison. The 2DH prediction is only expected to apply for finite fields, and the Fig. 2(a) curves are linear at higher fields up to magnetic saturation. In lower fields, the magnetization is linear in the field, and was used to obtain the zero-field susceptibilities already discussed. The 2D XY model equation of state prediction (using the predicted critical exponent $\delta=15$) is shown in Fig. 2(b). It fits the data fairly well over the entire temperature range, but especially near the kink temperature. Despite the absence of intermediate data, the 30 and 35 K M vs H curves indicate a Kosterlitz–Thouless transition could have occurred between them.

The 2D XY model is consistent with the presence of magnetization versus temperature peaks observed in very small field measurements. A magnetization versus temperature peak for the 500-Å sample was observed around 32.4 to 33.0 K. Although the low fields were probably nonuniform, they were constant. Since the magnetization is proportional to the field in sufficiently low fields, a peak probably demonstrates a finite temperature susceptibility divergence. It is not prominent, and is superimposed on a large monotonically increasing magnetization curve. At present only the approximate location of the peak is reliable. An exponentially diverging shape is expected of a Kosterlitz–Thouless transition, instead of the usual power law divergence. Stronger evidence of such a peak shape is seen in data for the thinner films ($L<500$ Å), but consistent reproduction of the results will require a magnetometer measuring in controllably uniform low fields. Confirmation of the peak and peak shape,

coupled with demagnetization-limited susceptibility below T_{peak} would indicate 2D XY model behavior prevailing below the kink temperature.

IV. CONCLUSIONS

The 2D Heisenberg and 2D XY model behaviors are functionally similar. Consequently, magnetization $M(H)$ and susceptibility $\chi(T)$ for both models can be fitted to all the data. However, the model behaviors are distinguished by the kink in the 2DH plot of $\ln(\chi)$ vs $1/T$. Also, no susceptibility or magnetization peaks are seen at the temperature for which the susceptibility kink occurs, whereas a magnetization peak is observed at a lower temperature that could correspond to a Kosterlitz–Thouless transition.

For thinner films[1,2] the total range of temperature for both regions is greater and the behaviors are more easily distinguished, but the signal-to-noise ratios are proportionately worse, and low-temperature behavior in the thinnest films is more difficult to obtain experimentally. The 500-Å film also has the advantage of sufficient signal strength to observe its behavior up to and somewhat above the bulk Pd(1.2 at. % Fe) $T_c \approx 40$ K, thus connecting it to bulk Pd(Fe) results. The films described here were polycrystalline. Better film growth is currently being pursued, to increase the crystal size and determine if the boundaries between the different model behaviors become more sharply defined.

The effects of frustrated biquadratic interactions on the phase diagrams and criticality of the Blume–Emery–Griffiths model (abstract)

Daniel P. Snowman and Susan R. McKay
Department of Physics and Astronomy, University of Maine, Orono, Maine 04469

The Blume–Emery–Griffiths model, a spin-1 Ising model with bilinear (J), biquadratic (K), and the crystal field (Δ) terms, provides a general system for the study of both density and magnetic fluctuations. Previous work has shown that a rich variety of phase diagrams occurs in cases of positive[1] or negative[2] biquadratic coupling. In this study, we consider an exactly solvable system in which frustration is present due to competing biquadratic interactions. Thus, this calculation models a dilute ferromagnetic mate ial with two types of nearest neighbor site pairs, distinguished by whether or not simultaneous occupation is energetically favored. To determine the effects of this competition, we have constructed exactly solvable frustrated hierarchical models similar to those introduced to study spin glasses.[3] The resulting phase diagrams show that, when frustration is present, the dense disordered and dilute disordered phases can become separated by a phase with chaotic rescaling of K and Δ. In the $J=0$ plane, this chaotic rescaling is directly linked to that previously reported in spin glasses[3] via the Griffiths symmetry.[1,4]

Magnetic phase transitions in $CsEr(MoO_4)_2$ and $KDy(MoO_4)_2$-chain-layered Ising compounds (abstract)

E. N. Khats'ko and A. S. Cherny
Institute for Low Temperature Physics & Engineering, Ukraine Academy of Sciences, 47 Lenin Avenue, Kharkov 310164, Ukraine

The crystals investigated belong to the family of the orthorhombic layered rare-earth double molybdates. These crystals have aroused interest because of the diversity of structural and magnetic phase transitions, which are due to the crystalline structure and the electron energy spectrum of rare-earth ions. These ions are distinguished for their Ising behavior. The magnetization and susceptibility measurements were performed at temperatures between 0.5 and 300 K in magnetic fields up to 0.4 T along three principal magnetic axes. The 3D magnetic ordering is found to occur at $T_c=0.84$ K for $CsEr(MoO_4)_2$ and $T_c=1.1$ K for $KDy(MoO_4)_2$. The magnetic properties are strongly anisotropic both above and below T_c. In the magnetic ordered state spin-orientation phase transitions were found in both of these compounds. For $CsEr(MoO_4)_2$ a typical metamagnetic transition was observed along one magnetic field direction (b). There is a more intricate situation in the case of $KDy(MoO_4)_2$. The spin-orientation phase transition has a rather complex character: it is anitferromagnetic along the a axis, and ferromagnetic along the b and c axes. The magnetic structures of these compounds were determined. In the case of $CsEr(MoO_4)_2$ a collinear two-sublattice structure of antiferromagnetically ordered ferromagnetic chains is realized. For $KDy(MoO_4)_2$, the magnetic structure is defined as a complicated noncollinear four sublattice structure with magnetic moments rotated 35° in the ac plane and 10° in the bc plane.

Na-doping effect on the magnetic properties of the YBCO ceramics

T. Nurgaliev, S. Miteva, I. Nedkov, A. Veneva, and M. Taslakov
Institute of Electronics, Bulgarian Academy of Sciences, 72 Blvd. Tzarigradsko Chaussee, 1784 Sofia, Bulgaria

The ac magnetization and the microwave surface resistance (at 12 GHz) were measured on a series of Na-doped YBCO ceramic samples at 77 K. Their magnetic behavior was explained on the basis of the modified critical state model by taking into account the existence of a field-dependent component J_{c1} (due to weakly linked grains) and a field-independent component J_{c0} (due to perfectly linked grains) in the bulk critical current density of the samples. The Na and Cu remaining after the heat treatment of the samples changed the intergranular medium parameters and impeded the correlation between the grains. As a result, an increase of the Na concentration led to a decrease of the specimens critical current density and an increase of their surface resistance. At small Na concentrations, a certain increase of J_{c1} was observed, which can be explained by taking into account the possibility of partial pinning of Josephson vortices in the "weakly seeded" places in the intergranular media.

I. INTRODUCTION

The magnetic behavior of the YBCO ceramics is largely dominated by processes in the intergranular medium, and described in the framework of the modified critical state model[1,2] by taking into account the field dependence of the mean intergranular critical current density J_c. A particular form for the field dependence is usually assumed, and then the fitting parameters, corresponding to the components of the critical current density and the scaling field, are obtained from a comparison of the model calculation with the measured data.[3,4] The microwave losses in such samples are mainly determined by intergranular coupling whose efficiency depends on the properties of the intergranular medium.[5,6] The presence of some metals during the YBCO synthesis affects the properties of the intergranular medium[7] of the end product. One should expect as a result a modification of the magnetic and microwave parameters of these samples as compared with the undoped ones.

This paper deals with experimental investigation and interpretation of the changes in the magnetic and microwave characteristics of YBCO ceramic samples prepared in the presence of a Na additive.

II. EXPERIMENTAL

The samples were produced using the general formula $Y_{1-0.2x}Ba_{2-0.2x}Na_{0.4x}Cu_{3+0.3x}O_y$, where x varies from 0 to 2.00, which allows an overstoichiometric presence of Na_2O and traces of CuO on the grain boundaries in the YBCO ceramics.

The presence of Na_2CO_3 during the sintering process enabled us to obtain a highly homogeneous structure with low grain size. The physical measurements were carried out on disk-shaped samples with a thickness of about 1 mm and a diameter about 9 mm. To study a sample's screening properties, we placed the sample in an ac magnetic field (1 kHz) and the response signal was registered by an almost flat coil (ϕ 1.5×0.5 mm^2) located at the center of the high-temperature superconducting (HTSC) pellet. The screening parameter N was found by taking the ratio of the signal's amplitude measured at superconducting ($T=77$ K) and normal ($T=295$ K) state of the specimen. The surface resistance at 77 K was measured by means of Cu resonator structures formed on a thin dielectric substrate, with the HTSC pellet serving as a ground plate.[7]

To perform the critical current measurements, ϕ 1×9 mm^2 cylinders were cut from HTSC disks. The pick-up coil was tightly wound around the sample, and a phase-sensitive device was used to record the response signal.

III. INTERPRETATION OF THE MAGNETIC BEHAVIOR

To interpret the magnetic behavior of the ceramic sample at low magnetic fields (≤3 mT) the existence of two kinds of the intergranular contacts in the sample must be taken into account.[1-9] The local macroscopic intergranular critical current density J_{c1} for the weakly coupled grains nearly exponentially decreases with increasing of the local magnetic field[3,4] H, while the local macroscopic "bulk" critical current density J_{c0} remains unchangeable for the perfectly coupled grains.[9] By taking into account this, we assumed the following field dependence for the critical current density J_c in our samples

$$J_c=J_{c0}+J_{c1}/ch(H/H_c), \tag{1}$$

where H_c is the scaling field. When the external magnetic field H_α decreases from its maximum H_m to its minimum $-H_m$, the following solution of the critical state equation can be obtained:

$$h_1-h_m-C\ \ln[(e^{h_m}+A)(e^{h_1}+D)/(e^{h_m}+D)(e^{h_1}+A)] = J(x-1) \quad 0\leq x\leq x_t, \tag{2}$$

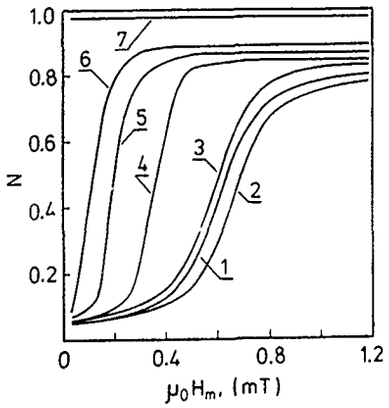

FIG. 1. The screening parameter N vs the magnetic field amplitude H_m for Na-doped YBCO pellets ($\phi 1\times 9$ mm^2) measured at 77 K. Curves 1–7 correspond to samples with initial Na concentrations $x=0$, 0.4, 0.75, 0.95, 1.2, 1.5, and 2, respectively.

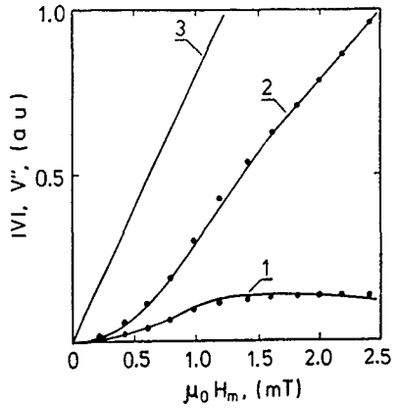

FIG. 2. Dependence of the response signal modulus (2) and the out-of-phase component (1) on the external-field amplitude H_m for a Na-doped ($x=0$ 4) YBCO sample ($\phi 1\times 9$ mm^2) measured at 77 K. The theoretical curves 1 and 2 (solid) are obtained by taking into account the J_c vs H dependence described by Eq. (1). The values of the fitting parameters are given in Table I. Curve 3 presents the $|V|$ vs H_m dependence for a sample in normal state (100 K).

$$h_2-h_\alpha-C\ \ln[(e^{h_\alpha}+A)(e^{h_2}+D)/(e^{h_\alpha}+D)(e^{h_2}+A)]$$
$$=-J(x-1)\quad x_i\leqslant x\leqslant 1, \tag{3}$$

where $h_1=H_1/H_c$ and $h_2=H_2/H_c$ are the dimensionless internal magnetic fields: $h_m=H_m/H_c$; $h_\alpha=H_\alpha/H_c$; $J=J_{c0}R/H_c$; $A=k+(k^2-1)^{1/2}$; $D=k-(k^2-1)^{1/2}$; $C=k/(k^2-1)^{1/2}$; $k=J_{c1}/J_{c0}>1$; $x=r/R$, r is the radial coordinate; $x_i=r_i/R$ is the dimensionless coordinate where the shielding current changes its direction and $H_1(x_i)=H_2(x_i)$. By solving Eqs. (2) and (3), one can find the magnetic field profile in the sample and calculate the total magnetic flux ϕ which penetrates it. For a harmonic external field $H_\alpha=H_m\cos(\omega t)$ (where ω is the angular frequency), the basic component of the total magnetic flux ϕ_ω can be expressed as follows:

$$\phi_\omega=\phi'_\omega\cos(\omega t)-\phi''_\omega\sin(\omega t)$$
$$=\pi R^2H_m(\mu'\cos(\omega t)-\mu''\sin(\omega t)$$
$$=\pi R^2H_m[(\chi'+1)\cos(\omega t)-\chi''\sin(\omega t)], \tag{4}$$

where ϕ'_ω and ϕ''_ω are the in-phase and out-of-phase components of the magnetic flux, which can be obtained from $\phi(t)$ by means of a Fourier transform; μ', μ'', χ', and χ'' are the real and imaginary components of the specimen's dynamic permeability and susceptibility. Signals proportional to $|\phi_\omega(H_m)|$, $\phi'_\omega(H_m)$, and $\phi''_\omega(H_m)$ are registered experimentally. Further, by comparing such theoretical and experimental dependences, one can find the optimal values of the parameters J_{c0}, J_{c1}, H_c corresponding to the real specimen characteristics.

IV. RESULTS AND DISCUSSION

Figure 1 presents the dependence of the screening coefficient N of HTSC pellets with various Na-additive amounts on the amplitude H_m of the external ac magnetic field. In specimens with small amounts ($x\leqslant 0.75$), the magnetic field begins to penetrate the intergranular medium at $\mu_0H\approx 0.5$ mT. A field of $\mu_0H\approx 1.0$ mT leads to a decrease in the intergranular critical current density and destroys the screening properties of the central zones of the pellet. At stronger fields $\mu_0H\geqslant 2.0$ mT, the screening effect is only due to the small number of "loops" consisting of perfectly linked grains and to the diamagnetism of the grains. The field starts penetrating the grains at $\mu_0H_g\geqslant 4.5$ mT. An estimate of the critical current density for the grains J_g using the above value for the field H_g (for YBCO at 77 K, the London penetration depth is ≈ 0.3 μm) yields $J_{cg}\sim H_g/\lambda\approx 10^6$ A/cm^2, a value typical for single-crystal YBCO samples. A worsening of the pellets screening properties is observed for higher initial Na concentrations ($x\geqslant 0.75$), but no noticeable drop of H_g is seen. This means that within the concentrations interval indicated ($0\leqslant x\leqslant 1.5$), the Na affects mainly the electrical parameters of the intergranular boundaries. At $x=2$, however, the sample becomes "transparent" to the magnetic field ($N\approx 0.97$) due to the strong suppression of the superconductivity in the grain themselves.

To determine the critical current density J_c, we used cylindrically shaped specimens with $R\approx 0.5$ mm. The dependences of the pick-up coil voltages modules $|V(H_m)|\sim|\phi_\omega(H_m)|$ and the out-of-phase component $V''(H_m)\sim\phi''_\omega(H_m)$ on the amplitude H_m of the external magnetic field was experimentally registered (Fig. 2). The values of the specimen's effective static permeability μ_c usually are 0.5–0.6. The initial value of J_{c0} was then found through fitting the theoretical dependence $|V(H_m)|$ (calculated for $J_{c1}=0$, the expressions are given in Ref. 8) to the experimental one measured at relatively large H_m values so that the contribution of the weak links current to the response signal is small but, at the same time, the field does not penetrate the grains. For the initial H_c value we assumed half of the field value which totally suppresses the weak link current. Further, the initial value of J_{c1} was obtained by fitting the theoretically calculated $|V(H_m)|$ dependence [Eqs. (1)–(4)] to the experimental one. The last procedure was then repeated with each of the parameters J_{c0}, J_{c1}, H_c varying within certain limits until good agreement was reached between the theo-

TABLE I. Characteristics of YBCO samples.

1.50	10	28	0.20	100

retical and experimental $|V(H_m)|$ and $V''(H_m)$ dependences. The sample characteristics found as described are presented in Table I.

Specimens with small Na-additive amounts ($x \approx 0.4$) exhibit some increase of the weak link critical current density J_{c1}, while the other two parameters J_{c0} and H_c stay practically unchanged. A further increase of the Na amount results in a decrease of all YBCO sample parameters and in their complete degradation at $x=2$. The behavior of the bulk sample electrical parameters is related to the properties of the intergranular boundaries. The critical current density J_c for a single-tunnel Josephson junction is proportional to the junction parameters Δ (the energy gap parameter) and R_n (the normal-state tunneling resistance).[6] $J_c \propto \Delta^2/R_n$. The R_n parameter is strongly affected by the distance between the junction boundaries.[6] After the heat treatment, the Na and Cu compounds are predominantly located on the surface of the YBCO grains and form a "surface layer" that can be characterized by a dielectric constant ϵ and a conductivity σ. A rise in the Na concentration leads to a drop in the critical current density at the expense of either an R_n increase (for an intergranular medium with $\sigma \approx 0$) or a gap parameter suppression (for an intergranular medium with $\sigma \gg 0$). Such a behavior of J_c, J_{c0}, and H_0 was in fact observed in YBCO for Na concentrations $x>0.75$. For small Na concentrations ($x \leqslant 0.75$), this "seeding" of the intergranular boundaries by Na compounds is insignificant. The small increases of the critical current density in the latter case can be explained by the possible pinning of Josephson vortices at the "seeded" points in the intergranular space.

The surface resistance R_s of the pellets increased with increasing x. If one assumes that the sample consists of weak links (i.e., the grain contribution to R_s is small), its surface resistance at weak fields will be proportional to $\omega^2\sigma/\lambda_J^3$, where λ_J is the Josephson penetration depth.[6] On the other hand, $\lambda_J \sim J_c^{-1/2}$, and, therefore, the surface resistance of the samples should increase as their critical current density decreases. Such a relationship is well observed experimentally in samples with $x \geqslant 0.75$; at smaller Na concentrations the R_s variation with x is not significant.

V. CONCLUSION

In the present work, the results are presented of measurements of the screening parameter N, the critical current density J_c, and the surface resistance R_s of YBCO samples prepared from initial batches containing various amounts of Na. The behavior of the intergranular critical current density J_c is interpreted by taking into account the presence of both weakly linked grains and of a small number of perfectly linked grains. The values of J_c and the behavior of its dependence on the field are determined by solving numerically the critical state equation and comparing the results with the experimental data. It is demonstrated that the Na and Cu compounds remaining in the samples after the heat treating process are predominantly located on the surface of the YBCO grains and impedes the correlation between the grains. As a result, an increase of the Na concentration leads to a decrease of the specimens' critical current density and an increase of their surface resistance. However, at low Na concentrations ($x<0.75$), a certain positive effect is observed in what concerns the critical current density J_c; this is probably related to the possibility of partial pinning of Josephson vortices in the "weakly seeded" places on the boundaries.

Polycrystalline samples of $Nd_{2-x}Ce_xCuO_{4-y}(0.0\leq x\leq 0.17)$ obtained from a sol-gel precursor were sintered below the eutectic temperature and reduced under different conditions. From the results of x-ray powder diffraction, the tetragonal T' structure is preserved for Ce content up to $x=0.17$. A decrease in the lattice parameter c and a small increase in the lattice parameter a are observed with increasing Ce concentration. Electrical resistance $R(T)$ measurements performed on reduced samples with $x\geq 0.12$ reveal superconducting behavior below $T\approx 25$ K. We also found that all reduced samples display a striking double resistive superconducting transition and that the zero resistance state is achieved through two distinct drops in $R(T)$ at upper and lower transition temperatures T_{ci} and T_{cj}. The upper transition temperature T_{ci} has a maximum for Ce concentration $x=0.14$, which is independent of the reduction process. The lower transition temperature T_{cj} is observed in reduced samples with Ce content $x\geq 0.14$ and decreases monotonically with increasing Ce concentration. Magnetic susceptibility measurements confirm bulk superconductivity in several reduced samples, and a significant diamagnetic contribution is only observed for temperatures below T_{cj}. The results are discussed within the framework of a granular superconductor model.

The discovery of superconductivity in compounds of $Ln_{2-x}M_xCuO_{4-y}$(Ln=Nd, Sm, Pr, Eu; M=Ce, Th)[1-5] has stimulated an intense effort in the study of their physical properties. Many features of these oxides are well known, although some fundamental aspects are either still not understood or controversial.

One of the doubts about these compounds concerns the quality of the samples studied. Usually, high quality samples with the same starting composition and subject to almost the same reduction process behave differently.[6] Some important questions regarding this situation are related to the doping process, i.e., the replacement of the Ln by Ce and the removal of oxygen which are necessary to induce superconductivity. As far as Ce doping is concerned, it is still somewhat controversial whether materials prepared in the range $0\leq x\leq 0.17$ actually form a solid solution. Based on x-ray diffraction analysis, Cava and collaborators[7] concluded that samples of $Nd_{2-x}Ce_xCuO_{4-y}$ $(0.0\leq x\leq 0.17)$ are true solid solutions. On the other hand, Lightfoot and collaborators[8] believe that there is only one superconducting phase in this range with a Ce content close to $x=0.165$.

Besides this structural issue, other points remain to be addressed. One of them is related to the nature of the double resistive superconducting transition which is frequently observed in $R(T)$ measurements and is identified by two sharp drops in the electrical resistivity before the zero resistance state is attained. It has been proposed by Peng *et al.*[9] that the double superconducting transition is due to the presence of two distinct superconducting phases, each with a different superconducting critical temperature. Another explanation for this feature assumes that the sample is composed of small superconducting islands connected through Josephson coupling.[10-12] By assuming this picture, the first transition is related to the intragrain transition while the second one is believed to be due to the coupling between the islands through Josephson junctions. The present work provides some new information regarding structural, magnetic, and transport properties of these electron-doped superconductors.

Polycrystalline samples of $Nd_{2-x}Ce_xCuO_{4-y}$ were prepared with a wide range of Ce concentrations $0.0\leq x\leq 0.17$ by means of the sol-gel process. Details of this chemical route for producing polycrystalline samples are discussed elsewhere.[12] The samples were sintered at 1000 °C, which is below the eutectic temperature of ≈1050 °C. Reduction was carried out under different conditions. This step is important in order to induce superconductivity in these materials, and it was performed in flowing He gas for 20 h at 950 °C, followed by fast cooling. We have prepared three different batches of samples: (1) unreduced samples, (2) samples cooled in 1 h after the reduction process, and (3) samples cooled in 2 h after the reduction process. Unreduced samples showed no evidence of superconductivity, while reduced samples showed superconductivity for Ce concentrations in the range $0.12<x<0.17$. All samples were analyzed by x-ray powder diffraction using a Rigaku RU-200B diffractometer. The x-ray patterns showed that the tetragonal T' structure (Nd_2CuO_4 type structure) is preserved for Ce content up to $x=0.17$ and no vestiges of additional phases have been found in any sample studied. The lattice parameters were obtained through the refinement of the corrected peaks utilizing a least-squares program. Magnetization measurements were performed using a commercial superconducting quantum interference device (SQUID) magnetometer from Quan-

tum Design. Electrical resistance measurements were performed with a Linear Research LR-400 ac impedance bridge operating at 16 Hz with variable excitation current.

The x-ray diffraction patterns for polycrystalline samples of $Nd_{2-x}Ce_xCuO_{4-y}$, $0.0 \leqslant x \leqslant 0.17$, showed, within our resolution, no vestiges of additional phases. The powder diffraction data have been used to extract the lattice parameters a and c for different Ce concentrations. These results are summarized in Table I. A careful observation of these results shows that the lattice parameter c decreases with increasing Ce content from $c=12.17(4)$ Å for Nd_2CuO_4 to $c=12.07(7)$ Å for the highest Ce concentration $x=0.17$. Also, from the results of Table I, one can see that the lattice parameter a is almost insensitive to the replacement of Nd by Ce. The dependence of the c lattice parameter on Ce concentration suggests that Ce substitutes for Nd in the T' structure. Such a replacement seems to be in complete agreement with the formation of a true solid solution and not, for example, with phase separation. This is supported by the fact that no drastic change in the lattice parameter c is observed, i.e., it decreases smoothly with increasing Ce content. This conclusion is in agreement with the proposition made by Cava *et al.*,[7] who have observed behavior similar to that shown in Table I for both lattice parameters. In addition, a very broad distribution of values for the lattice parameter c for $x \approx 0.15$ has been detected. If one assumes that there is no phase separation when Nd is replaced by Ce, as proposed by Lightfoot, *et al.*,[8] this means that the presence of the nonsuperconducting phases in these compounds needs to be explained by invoking another variable of these systems: the removal of oxygen. It is possible that the removal of oxygen of about 0.02 per formula introduces a defect structure in this series, generating two different regions within the samples, one of which is superconducting and the other of which is nonsuperconducting. Similar structural defects have been observed in polycrystalline samples of $La_{1.8}Sr_xCa_{1.2-x}Cu_2O_{6-y}$,[13] La_2NiO_{4-y},[14] and $La_2CuO_{4\pm y}$.[15]

The presence of at least one superconducting phase in these polycrystalline samples is somewhat reflected in macroscopic measurements such as electrical resistance and magnetic susceptibility. In order to place this in perspective, the temperature dependence of the electrical resistance and magnetic susceptibility has been measured in all samples described above. Typical curves of $R(T)$ and $\chi(T)$ are displayed in Fig. 1, which shows data for $Nd_{1.83}Ce_{0.17}CuO_{4-y}$ cooled in 2 h after the reduction process. It is evident that the $R(T)$ curve displays a double resistive superconducting transition in which the electrical resistance shows two abrupt drops in magnitude when the sample is cooled below 25 K. Such a feature has frequently been observed in these electron-doped superconductors[10–12] for samples with $x \geqslant 0.14$. For the sample shown in Fig. 1, the first drop in $R(T)$ occurs at an upper temperature $T_{c1} \approx 17$ K. At this temperature, a broad decrease of about 30% in the magnitude of $R(T)$ is observed down to a lower temperature $T_{cJ} \approx 6$ K, where a second sharper decrease in $R(T)$ occurs. This feature has been explained by assuming that these samples are comprised of two different phases: one which is superconducting and another one which is believed to be nonsuperconducting. When the temperature falls below T_{c1}, the superconducting transition takes place and a drop of about 30% in $R(T)$ is frequently observed. Below this temperature, the system does not attain the zero resistance state because the superconducting volume fraction is below the percolation threshold. In the temperature range between T_{c1} and T_{cJ} the samples are believed to be comprised of superconducting islands embedded in a nonsuperconducting host. At a lower temperature T_{cJ}, Josephson coupling takes place and the zero resistance state is usually achieved.[10–12]

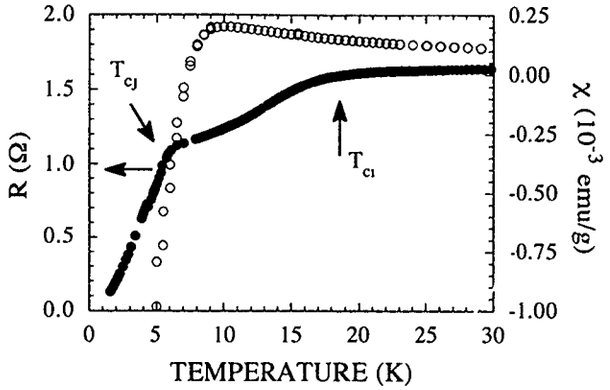

FIG. 1. Typical curves of $R(T)$ and $\chi(T)$ obtained on polycrystalline samples of $Nd_{2-x}Ce_xCuO_{4-y}$. These curves correspond to measurements performed on the sample with $x=0.17$ and cooled in 2 h after the reduction process. Arrows denote T_{c1} and T_{cJ} obtained from electrical resistance curves.

We believe that the brief discussion given above invalidates the presence of two superconducting phases in these electron-doped superconductors. If this were the case, the transition at T_{cJ} should not be very sensitive to changes in the excitation current and the application of a small magnetic field. However, several experimental results for these compounds reveal that below T_{cJ}, $\rho(T)$ is strongly dependent on these variables.[10–12] These results suggest that Josephson coupling develops at T_{cJ} and yield no evidence of two superconducting phases in this series.

Figure 1 is also useful for discussing the temperature dependence of the magnetic susceptibility in these compounds. Careful inspection of Fig. 1 reveals that significant diamagnetism only occurs below T_{cJ}. In fact, it is observed that the magnetic susceptibility is still increasing below T_{c1}, showing a paramagnetic-like behavior. When the temperature T_{cJ} is reached a transition occurs and the diamagnetic

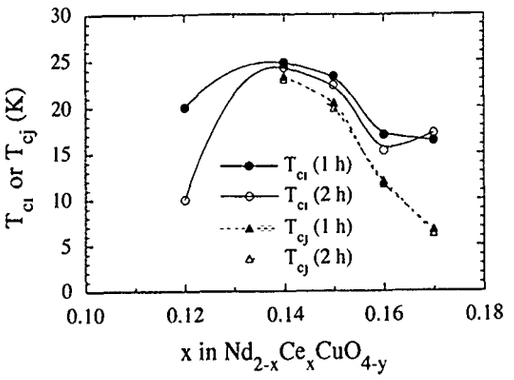

FIG. 2. Compositional dependence of T_{ci} and T_{cj} in a series of polycrystalline samples of $Nd_{2-x}Ce_xCuO_{4-y}$, $0.12 \leqslant x \leqslant 0.17$. The figure displays results obtained in two series cooled in either 1 or 2 h after the reduction process.

contribution becomes appreciable. The absence of appreciable diamagnetism between T_{ci} and T_{cj} indicates that superconducting properties must be confined to small regions, comparable with the London penetration depth. In fact, several results on polycrystalline samples of electron-doped superconductors are satisfactorily explained by assuming that superconducting properties are confined to small islands with typical size of 10–300 Å.[16–18]

Also of interest is the dependence of both T_{ci} and T_{cj} on Ce content in the $Nd_{2-x}Ce_xCuO_{4-y}$ series, $0.0 \leqslant x \leqslant 0.17$, which is shown in Fig. 2. From observations of Fig. 2 one can note that the transition temperature T_{ci} shows a maximum at $x=0.14$ and decreases at higher Ce concentration. It is also observed that T_{ci} is almost independent of cooling rate for $x \geqslant 0.14$ and is affected by the reduction process for $x=0.12$. On the other hand, the Josephson coupling temperature T_{cj} is almost insensitive to the reduction process in the Ce range studied. The qualitative behavior of T_{cj} obtained from electrical resistance measurements is in complete agreement with recent data of Singh *et al.*[19] even though they obtained T_{cj} from ac magnetic susceptibility measurements. This can be explained on the basis of the ac magnetic susceptibility data in this series that shows only one diamagnetic contribution which occurs at the Josephson coupling temperature.[16] In fact, our results for T_{ci} reveal remarkable differences with those of Ref. 19. They have observed from the electrical resistivity measurements that T_{ci} is almost constant for $0.14 \leqslant x \leqslant 0.17$. Our results show that T_{ci} has a maximum of ≈ 25 K at $x=0.14$ and decreases significantly for higher Ce content to 18 K for $x=0.17$. These discrepancies must be related to the sample preparation method used for making these materials.

From our results for $R(T)$ and $\chi(T)$ on polycrystalline samples of $Nd_{2-x}Ce_xCuO_{4-y}$, $0.0 \leqslant x \leqslant 0.17$, the behavior of these materials can be understood by using a model of a disordered array of small superconducting islands coupled through Josephson junctions. This is particularly evident from electrical resistivity measurements which show the striking double resistive superconducting transition. When the temperature decreases, the intergrain transition takes place and a drop in the magnitude of $R(T)$ is observed. This drop is not enough to drive the system to the zero resistance state, probably due to the very low superconducting volume. Additional decrease in temperature promotes the coupling of these superconducting islands below T_{cj}. At this temperature, the superconducting regions are believed to be coupled by Josephson effect and usually the system shows zero resistance. Due to the small size of these islands, comparable to the London penetration depth, an insignificant diamagnetic contribution to the susceptibility is observed between T_{ci} and T_{cj}. These superconducting islands become coupled together through Josephson junctions below T_{cj} and the diamagnetic contributions is appreciable.

In summary, we have performed x-ray powder diffraction, electrical resistance, and magnetic susceptibility measurements on polycrystalline samples of $Nd_{2-x}Ce_xCuO_{4-y}$, $0.0 \leqslant x \leqslant 0.17$, prepared from a sol-gel precursor. All of our x-ray results seem to agree with the proposition of Cava *et al.*,[7] since we have found no evidence of phase separation in this series. In addition, the macroscopic behavior of $R(T)$ and $\chi(T)$ can be fully explained by the assumption that all samples are comprised of small superconducting islands connected through Josephson junctions.

The magnetic ordering of the Pr ions in $Pb_2Sr_2PrCu_3O_8$ has been studied using neutron-diffraction and ac-suspectibility measurements. An imperfect three-dimensional magnetic ordering of the Pr spins was observed at a temperature well below its Neel temperature of $T_N \approx 7$ K. The magnetic intensities observed at $T=1.4$ K can be explained by assuming long-range order in the *ab* plane with short-range correlations, of correlation length $\xi_c=20$ Å, along the *c* axis and a moment directed along the *c*-axis direction. The magnetic ordering is 2D in nature, and the basic magnetic structure consists of nearest-neighbor spins that are aligned antiparallel along all three crystallographic directions. The magnetic transition is also evident in the ac-susceptibility versus temperature measurements, where a cusp that is typical of antiferromagnetic ordering is clearly observed, which matches the T_N obtained by neutron diffraction.

Just like other high-T_c oxides, $Pb_2Sr_2PrCu_3O_8$ (Pr 2:2:1:3) also possesses a layered structure. From the crystallographic structural point of view, the major difference between Pr 2:2:1:3 and $PrBa_2Cu_3O_7$ (Pr 1:2:3) is the number of layers stacked along the *c*-axis direction. The structure of the former can be obtained by replacing the CuO-chain layer in the latter with two PbO layers and one Cu layer.[1] This replacement results in even more anisotropic physical properties for the 2:2:1:3 systems than for the 1:2:3 systems. The rare-earth atoms in the 2:2:1:3 systems form an orthorhombic sublattice, where $a \approx b$ and the nearest-neighbor distance along the *c* axis is more than four times that in the *ab* plane. It is thus clear that the crystallographic anisotropy naturally leads to highly anisotropic magnetic interactions, and two-dimensional (2D) behavior can be expected.

The 3D long-range ordering of the Pr spins has been observed in both the Pr 1:2:3 and $TlBa_2PrCu_2O_7$ (Pr 1:2:1:2) systems with anomalously high ordering temperatures.[2,3] Numerous observations have indicated that hybridization plays an important role in the Pr magnetism. If this is the case we should then expect the effect along the *c*-axis direction to be much reduced in the Pr 2:2:1:3 system compared to the Pr 1:2:3 and Pr 1:2:1:2 systems, simply because of its wider spacing along the *c* axis. The Pr 2:2:1:3 system is then a better candidate for observing the 2D character of the Pr ordering. In this paper we report an imperfect 3D ordering of the Pr spins observed in Pr 2:2:1:3. The Pr spins ordered at 7 K, nevertheless even at $T=1.4$ K, the correlations between the Pr spins along the *c*-axis direction are still short range. The basic magnetic structure consists of Pr spins that are aligned antiparallel along all three crystallographic directions. The antiferromagnetic ordering of the Pr spins is also evident in the ac-susceptibility versus temperature measurements, where a cusp, typical of antiferromagnetic ordering, in the χ_{ac} vs T curve is clearly evident.

A powder sample of $Pb_2Sr_2PrCu_3O_8$ was prepared by the standard solid-state reaction technique, and the details can be found elsewhere.[4] Both x-ray and high-resolution neutron diffraction were used to characterize the sample. The nearest-neighbor distances between the Pr atoms that we obtained at room temperature were 3.815(1) Å and 15.765(4) Å in the *ab* plane and along the *c*-axis direction, respectively. The nominal oxygen concentration determined from neutron profile refinement analysis was 8.01(2). During the course of the low-temperature neutron-diffraction experiment, the sample was sealed in a cylindrical holder filled with helium exchange gas to promote thermal conduction at low temperatures. A pumped ^{4}He cryostat was used to cool the sample, and the lowest temperature achieved was 1.4 K.

Neutron-diffraction measurements were performed at the Research Reactor at the U.S. National Institute of Standards and Technology. The data were collected using the BT-9 triple-axis spectrometer operated in double-axis mode. The incoming neutrons had a wavelength of 2.352 Å defined by a pyrolytic graphite PG(002) monochromator, with a PG filter placed after the monochromator position for suppressing higher-order wavelength contaminations. The angular collimations used were 40′ in front of the monochromator, and 48′-48′ before and after the sample position, respectively. No analyzer crystal was used in these measurements.

The magnetic signal was isolated from the nuclear one by subtracting the data collected at high temperatures from the data taken at low temperatures.[5] Figure 1 shows the magnetic Bragg peaks thus obtained at $T=1.4$ K, where the diffraction pattern taken at $T=15$ K, serving as the nonmagnetic "background," has been subtracted from the data. The indices shown are based on the Pr chemical unit cell. The underlying spin structure of Pr hence consists of the nearest-neighbor spins that are aligned antiparallel along all three crystallographic directions. This is the same type of spin structure found in Pr 1:2:3[2] and Pr 1:2:1:2.[3]

The widths of the observed magnetic peaks are much broader than the instrumental resolution, which indicates a short-range ordering of the Pr spins. Short-range correlations along the *c*-axis direction and long-range correlations within the *ab* plane can be expected, since the nearest-neighbor dis-

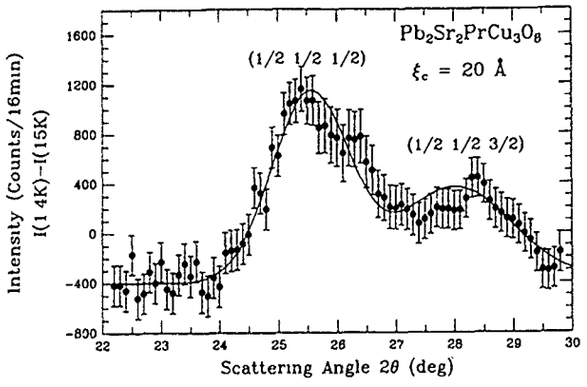

FIG. 1. Magnetic intensities observed in $Pb_2Sr_2PrCu_3O_8$ at $T=1.4$ K, where the indices shown are based on the Pr chemical unit cell. The Pr spins order antiferromagnetically along all three crystallographic directions. The solid curve is a fit to the data assuming long-range order in the *ab* plane and a short-range correlation length $\xi_c=20$ Å along the *c* axis.

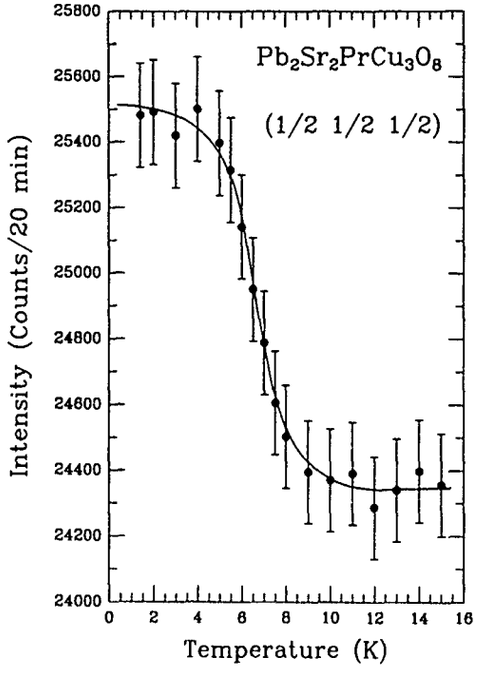

FIG. 2. Temperature dependence of the $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ peak intensity. The data reveal a typical order parameter with an ordering temperature of $T_N\approx7$ K. The solid curve is only a guide to the eye.

tance along the *c* axis is more than four times that in the *ab* plane. The solid line shown in Fig. 1 is a fit to the theoretical curve, assuming long-range correlations in the *ab* plane and short-range correlations, with a correlation length $\xi_c=20$ Å, along the *c* axis and a moment pointed along the *c*-axis direction. In generating the fitted curve we adopt Warren's approach [6] of averaging the scattered intensity for a 2D powder sample over all possible orientations in reciprocal space, and in addition allow for the presence of finite correlations along the third axis.[7] In comparison with the Pr ordering in Pr 1:2:3 and Pr 1:2:1:2, the Pr-Pr coupling remains antiferromagnetic and the 2D character becomes more pronounced in Pr 2:2:1:3 likely due to the larger spacing between the Pr-Pr atoms along the *c* axis. This crystallographic character results in a reduction of the hybridization between the Pr ions that are mediated through the copper-oxygen layers between them.

Figure 2 shows the temperature dependence of the $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ peak intensity, and reveals a typical order parameter with a Neel temperature of $T_N\approx7$ K. This ordering temperature of the Pr spins is a factor of 2 smaller than that found in Pr 1:2:3:7 ($T_N\approx17$ K) and is close to that found in Pr 1:2:1:2 ($T_N\approx8$ K). The ordering temperature of Pr is still much too high for purely dipolar interactions to explain.

The ac-susceptibility measurements were performed using a Lake Shore 7221 ac susceptometer. Data were collected with an alternating magnetic field of strength 1 Oe and frequency 250 Hz. A portion of the real part of the measured $\chi_{ac}(T)$ is shown in Fig. 3(a), and the temperature dependence of its derivative $d\chi_{ac}/dT$ is shown in Fig. 3(b). The magnetic transition is clearly seen with a $T_N\approx7$ K determined to be at the relative minimum in the $d\chi_{ac}/dT$ vs T plot. A cusp in the χ_{ac}-T curve, which is typical of antiferromagnetic ordering,[8] is also evident. These results are consistent with that obtained from neutron-diffraction measurements. We note that negative values for χ_{ac} were obtained on the high-temperature side shown in Fig. 3(a). This is due to the Meissner diamagnetism of the superconducting state present in the compound. The interplay between the Pr magnetism and superconductivity is the subject in a separate study.[9]

In conclusion, we have studied the magnetic ordering of the Pr spins in Pr 2:2:1:3 by neutron-diffraction and ac-susceptibility measurements. At $T=1.4$ K, which is well below the observed ordering temperature of $T_N\approx7$ K, an im-

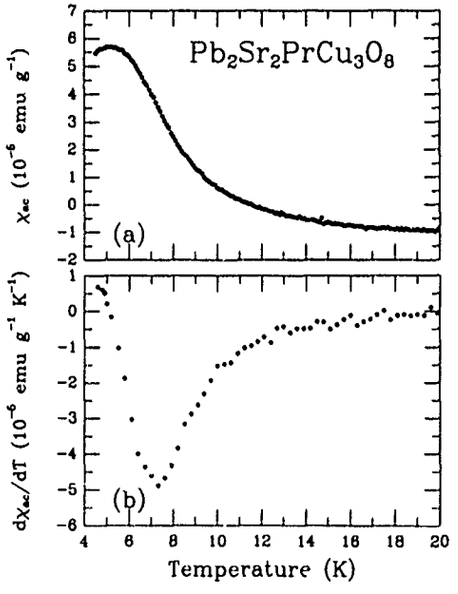

FIG. 3 A portion of the measured ac susceptibility $\chi_{ac}(T)$ and its temperature derivative $d\chi_{ac}/dT$ plotted against temperature. The transition temperature is determined to be at the relative minimum in the $d\chi_{ac}/dT$ vs T plot, which gives $T_N\approx7$ K. This T_N is consistent with the ordering temperature obtained from the data shown in Fig. 2.

perfect 3D ordering of the Pr spins was observed, with long-range correlations in the *ab* plane and short-range correlations along the *c* axis. The 2D behavior is believed to arise naturally from the crystallographic structure, and results in a reduction of the hybridization between the Pr ions in the present system. The ordering temperature observed is still much too high for purely dipolar and RKKY interactions may be anticipated.

The Tb ions in the isostructural compound Tb 2:2:1:3 were found[10] to order at $T_N \approx 5.5$ K. Even at $T = 1.4$ K the ordering of the Tb spins is still purely 2D without any correlation found along the *c* axis. It is then clear that, in the 2:2:1:3 system the coupling between the Pr atoms is much stronger than between the Tb atoms along all three crystallographic directions. Moreover, short-range correlations between the Pr spins have also been observed[11] in the $PrBa_2Cu_3O_{6.2}$ compound, which suggests that the oxygen concentration may also have important influence on the Pr hybridization along the *c* axis. A study of the effects of the oxygen concentration on the Pr ordering in the 2:2:1:3 system should give further information on the nature of the Pr hybridization.

Annealing temperature and O_2 partial pressure dependence of T_c in $HgBa_2CuO_{4+\delta}$

Q. Xiong, Y. Cao, F. Chen, Y. Y. Xue, and C. W. Chu
Department of Physics, Texas Center for Superconductivity at the University of Houston, Houston, Texas 77204-5932

Samples of $HgBa_2CuO_{4+\delta}$ (Hg-1201) were annealed under various conditions. After carefully controlling annealing time, annealing temperature (T_a), and O_2 partial pressure (P_0), we were able to find the reversible annealing conditions for Hg-1201. Under 1 atm O_2 at 260 °C$\leq T_a \leq$400 °C, the obtained T_c is nearly the same (~97 K). However, it decreases quickly with T_a>300 °C in high vacuum ($P_0 \sim 10^{-8}$ atm), and reaches zero at T_a=400 °C. On the other hand, T_c decreases with the decrease of T_a in high-pressure O_2 (~500 atm) and reaches ~20 K at about 240 °C. In the entire annealing region, the oxygen surplus varies significantly from 0.03 to 0.4, and a wide range of T_c variation (0→97 K→20 K) was obtained with anion doping alone.

Hg-1201 has a very simple crystal structure[1] and the highest T_c (~97 K at the optimal doping level) among all the single CuO_2-layer high-temperature superconductors (HTSs). Its simplicity makes it an ideal system for use in verifying theoretical models. For this purpose, doped samples with a wide T_c range to cover both the insulator-superconductor transition on the underdoped side and the superconductor-metal transition on the overdoped side are desirable. Many groups around the world raced to achieve that by annealing the as-synthesized samples in reduced or oxygenated gases. However, only limited results have been reported so far, partially due to Hg loss in this compound at elevated temperatures. Wagner *et al.*[2] reached T_c~50 K through reducing annealing in Ar at 500 °C. Itoh *et al.*[3] report at high-pressure O_2 annealing only produced a moderate change of T_c (~85 K on the overdoped side). The search for a wider T_c range has been obstructed by the decomposition of the compound above 500 °C. By studying the stability and the oxygen balance conditions, we explored a much wider annealing temperature-oxygen pressure region. The reversible annealing conditions were established. We obtained underdoped samples with T_c as low as zero (insulator) and heavily overdoped samples with T_c~20 K. In other words, the obtained samples cover nearly the whole insulator-superconductor-normal metal phase region. This enables us to further study the superconductivity of this compound in detail.

Hg-1201 samples were prepared by reacting a precursor pellet of Ba_2CuO_x and a composite Hg source. The precursor pellet is obtained by mixing appropriate amounts of BaO and CuO in an alumina crucible in a flowing mixed gas of Ar:O at a ratio of 4:1 at 930 °C for a total of 24 h with intermittent grinding once every 8 h. The composite Hg source used in this study was a prereacted Hg 1:2:0:1 pellet made by compacting the thoroughly mixed HgO and pulverized precursor powder. A small precursor pellet and a large composite Hg source are sealed inside an evacuated quartz tube, heated to about 810 °C and kept at this temperature for 8 h before being cooled to room temperature. Samples with different oxygen content were obtained by heating the as-synthesized samples at different temperatures and oxygen partial pressures for appropriate periods of time. Underdoped samples were prepared by heating the sample in vacuum at temperatures between 250 and 500 °C for 20–80 h. Overdoped samples were obtained by heating the as-synthesized compound for 10–240 h at temperatures between 240 and 400 °C and at an oxygen pressure that was between 1 and 500 bar. The structure was characterized by x-ray powder diffraction (XRD) and neutron powder diffraction (NPD). T_c were determined by both the dc magnetic susceptibility method using a Quantum Design superconducting quantum interference device (SQUID) magnetometer and the electrical resistivity method using the standard four-probe technique.

We knew beforehand that there are two things which may effect the T_c of Hg-1201, oxygen content and mercury loss. We tried to find annealing conditions which allowed any changes in sample structure and T_c to remain reversible. We found that long annealing times and high temperatures lead to mercury loss and sample decomposition. Figure 1(a)

is the data taken from a sample immediately after it was synthesized. It is almost single phase. Figure 1(b) is data taken from a sample after annealing in Ar at 500 °C for 20 h. A small amount of impurities show up. Figure 1(c) is data taken from a sample after annealing in Ar at 500 °C for about four days. Many impurities now appear. After carefully controlling annealing time and temperature, we were able to find the reversible annealing conditions for Hg-1201. Some typical x-ray data are shown in Fig. 2. Figure 2(a) was taken before annealing and Fig. 2(b) was taken after three days of annealing in vacuum at 400 °C. These data indicate that the sample still had a single Hg-1201 phase after the anneal. The slight shift in the peaks was caused by the change in lattice parameters that arose from the change in oxygen content of the sample. It is clear that the change in structure is reversible under these conditions.

Figure 3 shows resistivity data for one of our samples. Line 1 is data taken from the sample immediately after it was synthesized. Line 2 is data taken after a 240 °C, high-pressure ($P=500$ bar) anneal. After this, we annealed the sample again in one atmosphere of oxygen at 300 °C. Resistivity data taken after this second annealing are plotted here as line 3. These data show that the change in T_c was reversible and the T_c drop was caused by oxygen doping alone. The small transition broadening and change in resistivity were probably due to mercury loss between boundaries. The Meissner effect of this sample, which is shown in the inset of Fig. 3, is also consistent with this point.

The reversible annealing conditions are summarized in Fig. 4. The annealing time t, which should be long enough to let oxygen reach an equilibrium state but avoid significant Hg loss, is about 10–240 h, depending on the annealing en-

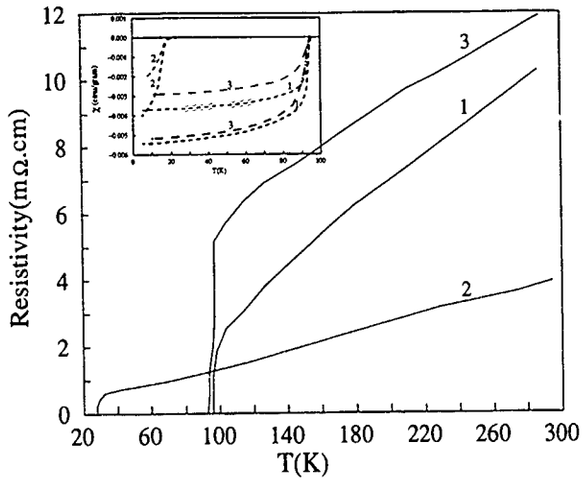

FIG. 3. Typical resistivity data taken from our Hg-1201 samples. Line 1 was taken immediately after the sample was synthesized Line 2 shows data taken after a 240 °C, high-pressure ($P=500$ bar) anneal Line 3 was taken after an anneal in 1 atm of oxygen at 300 °C.

vironment. The T_c corresponding to the desired T_a- $\log P_0$ conditions are obtained by interpolation. From the thermodynamic viewpoint an increase in annealing temperature should result in a decrease in oxygen content if the oxygen partial pressure is held constant. An increase in oxygen content should result from an increase in oxygen partial pressure if the annealing temperature is kept constant. When the sample is annealed in vacuum (10^{-8} atm) T_c decreases when the oxygen content decreases. This indicates that the sample is in its underdoped region. T_c increases with increasing annealing temperature when the sample is annealed in high-pressure oxygen ($5\times10^{+2}$ atm). This means that the sample is in the overdoped region. T_c is nearly the same over the range 250–400 °C in 1 atm of pure O_2. We were able to obtain T_c's ranging from 0 in the underdoped region to 97 K (optimal), then back down to 20 K in the overdoped region. According to an earlier study,[4] when the oxygen partial pressure is changed from 1 to 10^{-5} atm the oxygen content changes by about 0.4 for Y123. This means that the oxygen content is sensitive to the oxygen partial pressure in

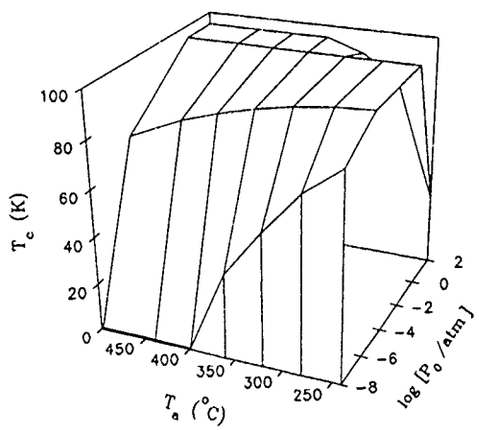

FIG. 4 3-D T_c vs (T_a, $\log P_0$) for Hg-1201.

$YBa_2Cu_3O_{7-\delta}$ (Y123). Comparing the annealing conditions with our thermogravimetric analysis and NPD results,[5] we found that when P_0 changes from $5\times10^{+2}$ to 10^{-8} atm, δ changes by about 0.4. This shows that the δ range is $0<\delta<0.4$, which is similar to that in Y123 but depends only weakly on P_0, which contrasts with Y123. The carrier concentration p has been determined, based on the room-temperature thermoelectric power and roughly follows $p\sim0.72\delta$; details will be published elsewhere.[5]

In summary, we have explored the reversible annealing conditions for Hg-1201 and obtained a T_c that covers the widest variation ever by anion doping only. Though the δ range in Hg-1201 is similar to that in Y123 we found that the sensitivity of δ to changes in oxygen partial pressure is much smaller than in Y123.

Penetration of electromagnetic fields into superconductors with gradual resistive transition

I. D. Mayergoyz
Electrical Engineering Department and Institute for Advanced Computer Studies, University of Maryland, College Park, Maryland 20742

The penetration of electromagnetic fields into superconductors is studied for the case of gradual resistive transition described by the "power law." Simple self-similar solutions are first found, which are then used to further generalize the Bean (critical state) model of superconducting hysteresis.

It is well known that models for superconducting hysteresis are based on the analytical study of penetration of electromagnetic fie! ıo hard superconductors. In the critical state model,[1,2] this study is performed under the assumption of ideal (sharp) resistive transition. However, actual resistive transitions are gradual and it is customary to describe them by the following power law:

$$E=\left(\frac{J}{k}\right)^n \quad (n>1), \tag{1}$$

where E is electric field, J is current density, and k is some parameter which coordinates the dimensions of both sides in expression (1).

The exponent "n" is a measure of the sharpness of the resistive transition and it may vary in the range 4–1000. Initially, the power law was regarded only as a reasonable empirical description of the resistive transition. Recently, there has been a considerable research effort to justify this law theoretically. As a result, models based on Josephson-junction coupling,[3] sausaging,[4] and spatial distribution of critical current[5] have been proposed. In the paper, the power law is used as a constitutive equation for hard superconductors. It is easy to show (by using Maxwell's equations) that this constitutive relation leads to the following nonlinear partial differential equation for the current density:

$$\frac{\partial^2 J^n}{\partial z^2}=\mu_0 k^n \frac{\partial J}{\partial t}. \tag{2}$$

We shall first consider the solution of this equation for the following boundary and initial conditions:

$$J(0,t)=ct^p, \quad (t\geq 0, p>0), \tag{3}$$

$$J(z,0)=0 \quad (z>0). \tag{4}$$

It is worthwhile to note here that the choice of the above boundary conditions is dictated by considerations of finding simple analytical solutions. It may seem at first that these boundary conditions are of very specific nature. However, it can be remarked that these boundary conditions do describe a wide class of monotonically increasing functions as p varies from 0 to ∞ (see Fig. 1). It will be shown below that for all these boundary conditions the profile of electric current density as a function of z remains practically the same. This observation will suggest to use the same profile of electric current density for arbitrary monotonically increasing boundary conditions. This will result in very simple analytical solutions.

The initial-boundary value problem (2)–(4) can be reduced to the boundary value problem for an ordinary differential equation. This reduction is based on the dimensionality analysis of Eqs. (2) and (3). This analysis leads to the conclusion that the following variable is dimensionless:

$$\zeta=\frac{z}{t^m\sqrt{k^{-n}\mu_0^{-1}c^{n-1}}}, \tag{5}$$

where

$$m=\frac{p(n-1)+1}{2}. \tag{6}$$

By using this dimensionless variable, we look for the self-similar solution of initial boundary value problem (2)–(4) in the form

$$J(z,t)=ct^p f(\zeta), \tag{7}$$

where $f(\zeta)$ is a dimensionless function of ζ. By substituting Eq. (7) into Eq. (2), after simple transformations we end up with the following ordinary differential equation:

$$\frac{d^2 f^n}{d\zeta^2}+m\zeta\frac{df}{d\zeta}-pf=0 \tag{8}$$

It is apparent that $J(z,t)$ given by expression (7) will satisfy boundary and initial conditions (3) and (4) if f satisfies the boundary conditions:

$$f(0)=1, \tag{9}$$

$$f(\infty)=0. \tag{10}$$

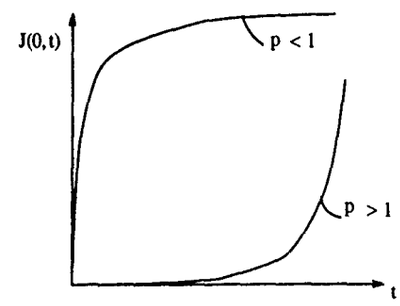

FIG. 1 Boundary conditions for the current density

 0021-8979/94/76(10)/7130/3/$6.00 © 1994 American Institute of Physics

Thus, the initial-boundary value problem (2)–(4) is reduced to the boundary value problem (8)–(10) for the ordinary differential Eq. (8). It can be proven that this nonlinear differential equation has the following group property: if $f(\zeta)$ is a solution to Eq. (8), then

$$F(\zeta)=\lambda^{-2/(n-1)}f(\lambda\zeta) \tag{11}$$

is also a solution to this equation for any constant λ. This property can be utilized as follows. Suppose that we have solution $f(\zeta)$ to Eq. (8) which satisfies the boundary condition (10), however

$$f(0)=a\neq 1. \tag{12}$$

Then, by using $\lambda=a^{n-1/2}$, we find that

$$f(\zeta)=\frac{1}{a}f(a^{(n-1)/2}\zeta) \tag{13}$$

is the solution to Eq. (8) which satisfies Eq. (10) as well as Eq. (9). Thus, we can first find a solution to Eq. (8) subject to boundary condition (10), then, by using transformation (11), we can map this solution into the solution which also satisfies the boundary condition (9).

It can be shown[6] that a solution to Eq. (8) satisfying the boundary condition (10) has the form

$$f(\zeta)=\begin{cases} b(1-\zeta)^{1/(n-1)}[1+b_1(1-\zeta)+b_2(1-\zeta)^2+\cdots], \\ \quad \text{if } 0\leq\zeta\leq 1, \\ 0, \quad \text{if } \zeta>1. \end{cases} \tag{14}$$

By substituting Eq. (14) into Eq. (8), after simple but lengthy transformations, we find

$$b=\left[\frac{m(n-1)}{n}\right]^{1/(n-1)}, \tag{15}$$

$$b_1=\frac{p(n-1)-m}{2mn(n-1)}, \tag{16}$$

$$b_2=-b_1\frac{1+\frac{1}{2}b_1[(2n-1)(3n-2)-4n]}{3(2n-1)}. \tag{17}$$

It is clear that

$$f(0)=b(1+b_1+b_2+\cdots)\neq 1. \tag{18}$$

This difficulty is overcome by using transformation (11) with

$$\lambda=[b(1+b_1+b_2+\cdots)]^{(n-1)/2}. \tag{19}$$

This leads to the following solution of the boundary value problem (8)–(10):

$$f(\zeta)=\begin{cases} (1-\lambda\zeta)^{1/(n-1)}\dfrac{1+b_1(1-\lambda\zeta)+b_2(1-\lambda\zeta)^2+\cdots}{1+b_1+b_2+\cdots}, \\ \quad \text{if } 0\leq\lambda\zeta<1, \\ 0, \quad \text{if } \lambda\zeta>1. \end{cases} \tag{20}$$

The last expression can be simplified by exploiting the fact that the exponent n in the power law is usually greater than 4. This simplification can be accomplished by using the following inequalities for b_1 and b_2 which can be easily derived from Eqs. (6), (16) and (17):

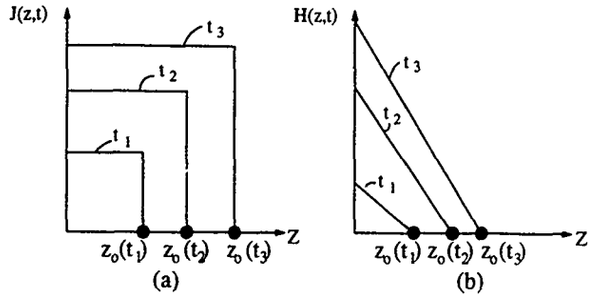

FIG. 2. Distributions of electric current density and magnetic field inside the superconducting half-space.

$$|b_1|\leq\frac{1}{2n(n-1)}, \tag{21}$$

$$|b_2|\leq\frac{1}{6(n-1)(2n-1)n}+\frac{1}{8(n-1)n}. \tag{22}$$

From the above inequalities, for $n\geq 4$ we find

$$|b_1|\leq 0.042, \quad |b_2|\leq 0.006. \tag{23}$$

This suggests the following simplification of solution (20):

$$f(\zeta)=\begin{cases} (1-\sqrt{m(n-1)/n}\,\zeta)^{1/(n-1)}, \\ \quad \text{if } 0\leq\zeta<\sqrt{n/m(n-1)}, \\ 0, \quad \text{if } \zeta>\sqrt{n/m(n-1)}. \end{cases} \tag{24}$$

By substituting Eq. (24) into Eq. (7) and taking into account Eq. (5), we end up with the following analytical expression for the current density:

$$J(z,t)=\begin{cases} ct^p\left(1-\dfrac{z}{dt^m}\right)^{1/(n-1)}, & \text{if } z\leq dt^m, \\ 0, \quad \text{if } z\geq dt^m, \end{cases} \tag{25}$$

where

$$d=\sqrt{(nc^{n-1})/[\mu_0 k^n m(n-1)]}\,. \tag{26}$$

The close examination of self-similar solution (25) leads to the following conclusion: in spite of the wide range of variation of boundary conditions (3) (see Fig. 1), the profile of electric current density $J(z,t)$ remains approximately the same. For typical values of n (usually $n\geq 7$), this profile is very close to a rectangular one. This suggests that the actual profile of electric current density will be close to a rectangular one for any monotonically increasing boundary condition $J_0(t)=J(0,t)$. Thus, we arrive at the following generalization of the critical state model.

Current density $J(z,t)$ has a rectangular profile with the height equal to the instantaneous value $J_0(t)$ of electric current density on the boundary of superconductor (see Fig. 2). Magnetic field $H(z,t)$ has a linear profile with a slope determined by instantaneous value of $J_0(t)$.

To better appreciate the above generalization, we remind that in the critical state model the current has a rectangular profile of constant (in time) height, while the magnetic field has a linear profile with constant (in time) slope.

For the zero front of the profile we have

$$z_0(t)=\frac{H_0(t)}{J_0(t)}. \tag{27}$$

However, $H_0(t)$ and $J_0(t)$ are not simultaneously known. For this reason, we intend to find $J_0(t)$ in terms of $H_0(t)$. To this end, we multiply Eq. (2) by z and integrate from 0 to $z_0(t)$ with respect to z and from 0 to t with respect to t. After simple transformations, we arrive at the following expression:

$$\mu_0 k^n \int_0^{z_0(t)} zJ(z,t)dz=\int_0^t J_0^n(\tau)d\tau. \tag{28}$$

By using in Eq. (28) the rectangular profile approximation for $J(z,t)$, we obtain

$$\frac{\mu_0 k^n}{2} J_0(t)z_0^2(t)=\int_0^t J_0^n(\tau)d\tau. \tag{29}$$

By substituting Eq. (27) into Eq. (29), we find

$$\frac{\mu_0 k^n}{2}\frac{d}{dt}\left[\frac{H_0^2(t)}{J_0(t)}\right]=J_0^n(t). \tag{30}$$

By introducing a new variable

$$\gamma(t)=\frac{H_0^2(t)}{J_0(t)}, \tag{31}$$

we can represent Eq. (30) as the following differential equation with respect to $\gamma(t)$:

$$\frac{d\gamma^{n+1}}{dt}=\frac{2(n+1)}{\mu_0 k^n} H_0^{2n}(t). \tag{32}$$

By integrating Eq. (32) and by using Eq. (31), we arrive at the following expression for $J_0(t)$:

$$J_0(t)=\frac{H_0^2(t)}{\{[(2(n+1)/\mu_0 k^n)]\int_0^t H_0^{2n}(\tau)d\tau\}^{1/(n+1)}}. \tag{33}$$

By substituting Eq. (33) into Eq. (27), we find the following expression for zero front $z_0(t)$ in terms of the magnetic field, $H_0(t)$, on th. boundary of superconductor:

$$z_0(t)=H_0(t)\left[\frac{2(n+1)}{\mu_0 k^n}\int_0^t H_0^{2n}(\tau)d\tau\right]^{1/(n+1)}. \tag{34}$$

This concludes our discussion of penetration of electromagnetic fields into superconductors with gradual resistive transition.

Study of the frequency and low-field dependence of ac susceptibility in YBaCuO

M. Zazo, L. Torres, J. Iñiguez, C. de Francisco,[a] and J. M. Muñoz[a]
Departamento de Física Aplicada, Universidad de Salamanca, E-37071 Salamanca, Spain

The frequency dependence of the ac susceptibility in polycrystalline samples of YBaCuO has been studied at the ac field range 0.06–1.2 Oe. The curve of the real part of the susceptibility χ' exhibits two drops, the first one close to T_c and the other well below T_c which could correspond to screening behavior of the grains and grain boundaries, respectively. The imaginary part of the susceptibility shows only a peak below T_c which is related to hysteresis losses at the grain boundaries. The peak corresponding to intragrains hysteresis losses is very small and appears masked by the losses of the intergrains. In the range of 1–20 kHz, the onset temperature of χ' showed no frequency dependence. However, the width of the transition decreases lightly and there is a small shift in the peak of χ'' to higher temperature as the frequency increases. This behavior could be explained in terms of the thermally activated Anderson flux creep. The shift depends on the amplitude of the measuring field. The activation energy for flux creep ranges from 6.4 eV at 0.02 Oe to 3.23 eV at 1.2 Oe in the zero-field-cooled measurements and from 3.41 eV at 0.02 Oe to 1.41 eV at 1.2 Oe in the field-cooled measurements.

I. INTRODUCTION

The ac-susceptibility method is one of the conventional methods used to study the properties of high-T_c superconductors (HTCSs).[1–5] In this paper, we present measurements of the zero-field-cooled and field-cooled ac susceptibility of HTCS samples as a function of the temperature, frequency, and ac magnetic field amplitude. The real part of the susceptibility χ' shows two drops and the imaginary exhibits only a peak. This peak is attributed to hysteresis losses at the intergrains. The peak corresponding to the intragrain is masked by the intergrain losses or is negligibly small in the frequency and field measuring range. The susceptibility shows strong dependence with ac magnetic field as well as with the measuring frequency. There is a small shift in the peak towards higher temperatures with increasing frequency in the 1–20 kHz range. However, the peak shifts to lower temperatures when the ac magnetic field increases from 0.02 to 1.2 Oe. These properties seem related to the dynamics of magnetic field flux motion in HTCS materials which is not yet completely understood.

The variation of the susceptibility with the frequency could be explained in terms of the flux creep at the grain boundaries. We have studied the behavior with the frequency following the Anderson theory[6] for conventional type-II superconductors, in which a flux vortex can jump the pinning barrier (flux creep) by means of the thermally activated phenomena. This effect is thought to be small in conventional type II superconductors with lower critical temperature, but at the considerably higher temperatures of HTCS it can be important. We calculate the flux creep activation energies at the grain boundaries in polycrystalline YBaCuO by the Anderson's model. As a reference point for specifying the temperature shifts with the frequency and the field we have used the temperature of the peak in χ''.

II. EXPERIMENTAL DETAILS

Polycrystalline samples of $YBa_2Cu_3O_x$ were prepared by the usual solid-state sintering method using CuO, $BaCO_3$, and Y_2O_3 as precursor materials. The ac susceptibility was measured by the mutual inductance method with the applied ac magnetic field parallel to the long axis of the specimen by means of a controlled current of variable frequency in the coil (5). Secondary voltage of a mutual induction is related to the susceptibility χ of the sample under test. Both the real χ' and imaginary part χ'' components of the complex susceptibility can be determined from the coil signal by phase sensitive techniques, such as a lock-in amplifier detector. However, we have measured directly the complex mutual inductance by a LCZ bridge:

$$\overline{M} = \frac{|Z|}{\omega}\text{sen}\left(\varphi+\frac{\pi}{2}\right)+j\frac{|Z|}{\omega}\cos\left(\varphi+\frac{\pi}{2}\right), \tag{1}$$

where $|Z|$ is the module of the impedance and φ is the phase angle measured by the bridge, and ω is the angular frequency. We can derive the two components of the ac permeability as

$$\mu' = -\frac{|Z|}{\omega K}\text{sen}\ \varphi, \tag{2}$$

$$\mu'' = -\frac{|Z|}{\omega K}\cos\ \varphi, \tag{3}$$

where K is a calibration coefficient for the coil geometry. The ac permeability components are related to the susceptibility terms as $\mu' = 1+\chi'$ and $\mu'' = \chi''$.

Zero-field-cooled measurements were made by cooling the sample at 77 K without any field while in the field-cooled measurement the sample was cooled under dc magnetic field (220 Oe) parallel to the long axis of the specimen and then the field was switched off. In both cases the measurements were taken while warming up the sample from 77 K to temperature over T_c in an ac field ranging from 0.02 to 1.6 Oe for frequencies from 1 to 20 kHz.

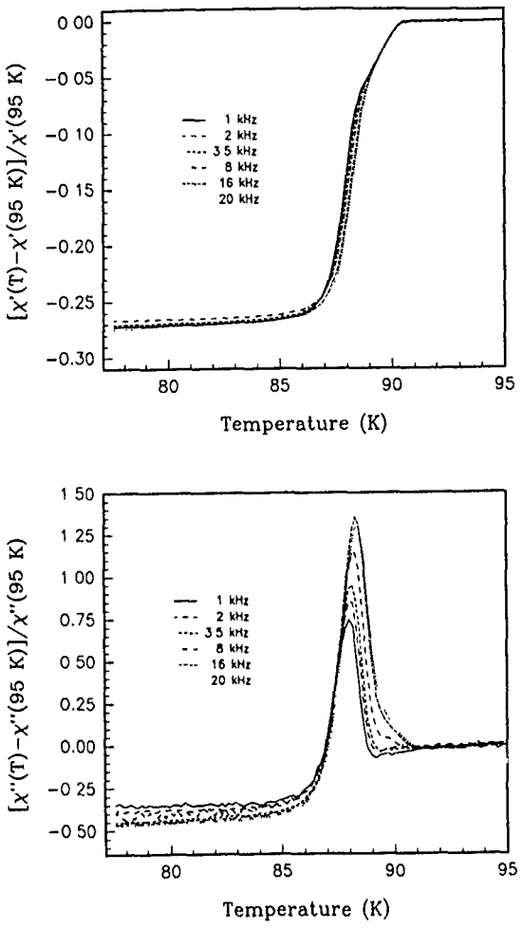

FIG. 1. χ vs temperature at different frequencies (h_{ac}=0.06 Oe).

III. RESULTS AND DISCUSSION

The susceptibility of the samples shows a typical dependence on temperature in which we can see two drops in the curve of the real part of the zero-field-cooled susceptibility χ_{zfc} (Fig. 1). In its turn, the curve of the imaginary part exhibits a peak corresponding to the drop in the lower-temperature region of χ_{zfc}, while the peak close to T_c associated with the intragrain losses is masked by the intergrain peak or it is very small (Fig. 1). The field-cooled susceptibility χ_{fc} presents similar results but the width of the diamagnetic transition in χ' increases, the peak broadens and the maximum of the χ'' shifts to lower temperatures.

Frequency dependence has been studied in the range 1–20 kHz at different ac magnetic fields parallel to the long axis of the specimen. The onset temperature of χ' was not modified by rising the frequency, however, the width of transition in χ' decreased lightly and there was a shift in the peak of χ'' to higher temperatures (Fig. 1). This seems a clear indication that the amount of magnetic flux penetrating the superconductor decreases with increasing frequency.

We have also studied the dependence with the ac magnetic field of the susceptibility of the samples in the range 0.02–1.2 Oe. The critical onset temperature of the diamagnetic transition does not change when increasing the magnetic field. However, the saturation of diamagnetic transition

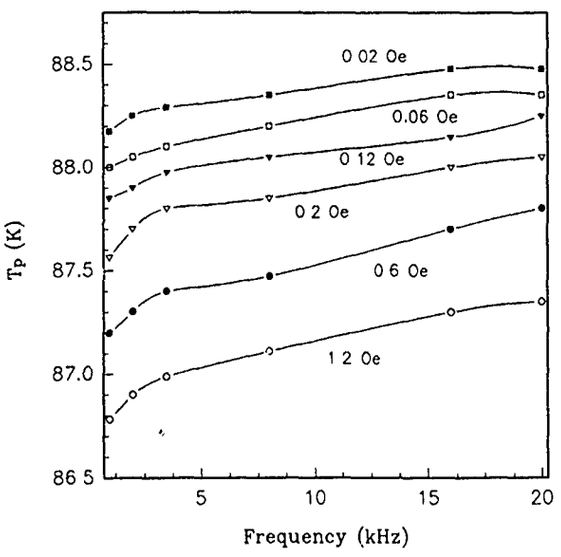

FIG. 2. T_p vs frequency at different ac magnetic fields.

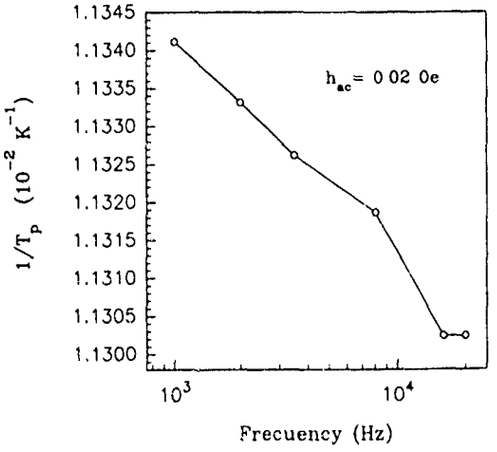

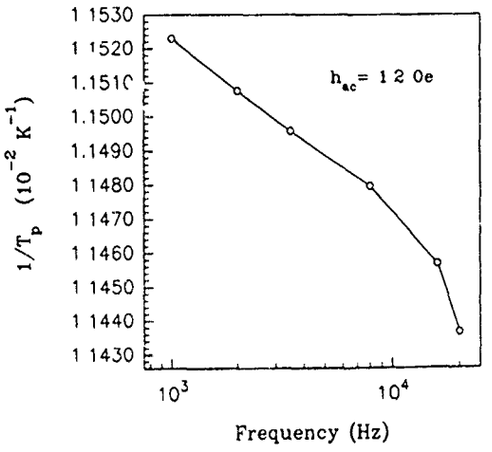

FIG 3. T_p^{-1} vs frequency at different ac magnetic fields

and the peak shift towards lower temperatures when the magnetic field increases, and furthermore the peak gets wider.

As was stated above, we have used the temperature of the peak (T_p) of χ'' for specifying the shifts with the frequency and ac magnetic field. Figure 2 shows the frequency dependence of T_p at different fields. T_p increases with the frequency and decreases with the magnetic field. This behavior could be explained by the thermally activated flux creep phenomenon proposed by Anderson for conventional type-II superconductors.[6] It is to be remarked that flux creep is thought to be a small effect in conventional type-II superconductor while in HTCS the thermally activated creep could have a significant effect.

According to the Anderson theory the jump over the pinning barriers is given by the usual Arrhenius expression

$$\nu = \nu_0 \exp(-U/k_B T), \tag{4}$$

where ν_0 is a characteristic frequency and U is an effective thermal activation energy, which includes a barrier height and a field-dependent force. Anderson and Kim[7] used the linear relation

$$U = U_0 - |\mathbf{F}| V a, \tag{5}$$

where U_0 was presumed to be the effective height of the energy barrier for thermally activated motion, $|\mathbf{F}|$ is the Lorentz force ($\mathbf{J}\times\mathbf{B}$), V is the activation volume, and a is the effective geometrical width of the energy barrier.

In Fig. 3 we plot $1/T_p$ vs ln ν for a field of 0.02 and 1.2 Oe, respectively. We have fitted these curves according to expression (4) to calculate the activation energy as a function of the magnetic field. The energies vary from 6.4 eV at 0.02 Oe to 3.23 eV at 1.2 Oe in the zero-field-cooled measurements. These values are comparable to those observed by Nikolo and Godfard[8] and by Dhingra and Das[9] with other measuring conditions. As the field increases, the Lorentz force ($\mathbf{J}\times\mathbf{B}$) increases, the thermal activation energy decreases and more flux vortices get depinned during the field cycle which is according to the Anderson–Kim model.

In a similar way we have measured the activation energy corresponding to χ_{fc}. In this case, the activation energy varies from about 3.41 eV at 0.02 Oe to 1.41 eV at 1.2 Oe. The activation energies are lower than in the zero-field-cooled measurements due to the effect of two contributions: the ac magnetic field and the dc magnetic flux trapped when the sample was cooled.

IV. CONCLUSIONS

The width of the diamagnetic transition decreases and the peak related with the intergrain losses shifts lightly to higher temperatures with increasing frequency. This could be demonstrative that the magnetic flux in the grain boundaries decreases with the increasing frequency. The shift of the peak in χ'' has been studied by means of the Anderson's theory of the flux creep. The activation energies take values in the range of 6.4–3.23 eV for applied field 0.02–1.2 Oe. These values of the activation energies decrease when the sample is cooled under a dc magnetic field.

Effects of Ga doping on the magnetic ordering of Pr in $PrBa_2Cu_3O_7$

Neutron-diffraction and ac-susceptibility measurements have been performed to study the effects of Ga doping on the magnetic ordering of the Pr in $PrBa_2(Cu_{1-x}Ga_x)_3O_7$. The Ga atoms preferentially replace the Cu atoms in the CuO-chain layers, and this substitution is found to decrease the antiferromagnetic ordering temperature as the Ga concentration is increased. In addition, the spin arrangement along the c axis is found to change from nearest neighbors being antiparallel for $x=0$ to nearest neighbors being parallel for $x=0.08$ (24% Cu chain substitution); for an intermediate x of 0.04 a mixture of the two spin structures is observed. The susceptibility results exhibit Curie–Weiss behavior above T_N, and departures from this behavior in the ordered state.

Among high-T_c oxides, $PrBa_2Cu_3O_7$ has attracted considerable attention because of its unexpected electric and magnetic properties. The introduction of Pr in $YBa_2Cu_3O_7$ suppresses superconductivity,[1,2] the Pr ions have a Neel temperature as high as 17 K, and an ordered moment as small as $0.74\mu_B$.[3] It is clear that interactions other than dipolar are responsible for the Pr magnetism. If superexchange is the dominant key, then those atoms located between the Pr atoms may also play important roles in Pr magnetism. An understanding of the coupling between the Pr atoms and the intermediate atoms located between them is then essential to a full understanding of the interactions involved.

There are three different types of layers of atoms that are located between the Pr atoms in $PrBa_2Cu_3O_7$: the CuO-chain layer, the CuO_2-plane layer, and the BaO layer. Metallic doping with Zn atoms, which substitutes for the Cu atoms located in the CuO_2-plane layers, causes the spin arrangement of Pr along the c axis to realign from antiparallel to parallel, without affecting its ordering temperature significantly.[4] On the other hand, a full replacement of the CuO-chain layers by TlO layers, i.e., $PrBa_2(TlCu_2)O_7$, does not alter the spin structure of Pr but reduces its ordering temperature by a factor of 2.[5]

In this paper we report neutron-diffraction and ac-susceptibility measurements made on the $PrBa_2(Cu_{1-x}Ga_x)_3O_{7-y}$ compounds to examine the effects of Ga doping on the ordering of the Pr spins. The Ga atoms replace the Cu atoms located in the CuO-chain layers. Two systems with $x=0.04$ and 0.08 (12% and 24% replacement, respectively) were studied, and we found that both the spin structure and the ordering temperature of Pr ions are sensitive to the presence of Ga atoms. The ordering temperature decreases with increasing Ga doping, and the nearest-neighbor spins along the c axis have the tendency to realign from antiparallel to parallel.

Powder samples of $PrBa_2(Cu_{1-x}Ga_x)_3O_{7-y}$ were prepared by the standard solid-state reaction technique, the details of the sample preparation techniques can be found elsewhere.[6] Both x-ray and high-resolution neutron diffractions were used to characterize the samples. The nominal oxygen concentration, determined from neutron profile refinement analysis,[7] is 6.98(4) and 6.96(4) for the $x=0.04$ and 0.08 compounds, respectively. Neutron-diffraction measurements were performed using the BT-9 triple-axis spectrometer at the Research Reactor at the U. S. National Institute of Standards and Technology. A pyrolytic graphite PG(002) monochromator was employed, with a PG filter placed after the monochromator position to suppress the higher-order wavelength contaminations. The energy of the incident neutrons was 14.8 meV (2.352 Å), and the angular collimations before and after the monochromator and after the sample were 40′, 48′, and 48′ full width at half maximum (FWHM), respectively. No analyzer crystal was used in these measurements. For the low-temperature experiments, the sample was mounted in a cylindrical aluminum can filled with helium exchange gas to facilitate thermal conduction. A pumped ^{4}He cryostat was used to cool the samples, and the lowest temperature obtained was 1.36 K.

A standard subtraction technique[8] was used to isolate the magnetic signal from the nuclear one, where the diffraction pattern taken at a temperature well above the ordering temperature was subtracted from the one taken at low temperature. Figures 1(a) and 1(b) show the magnetic Bragg peaks observed at low temperatures for the $x=0.04$ and 0.08 compounds, respectively. The indices shown are based on the chemical unit cell. Both the $\{\frac{1}{2}\frac{1}{2}0\}$ type and the $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ type of reflections are needed in explaining the data shown in Fig 1(a). If only one reflection is assumed for the peak that occurs at around $2\theta=25°$, it turns out that not only the width of this peak is much too broad in comparison with the instrumental resolution but the peak position also would fit neither to the $\{\frac{1}{2}\frac{1}{2}0\}$ reflection nor to the $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ reflection. In addition, the presence of the $\{\frac{1}{2}\frac{1}{2}1\}$ and $\{\frac{1}{2}\frac{1}{2}\frac{3}{2}\}$ reflections suggests the existence of the $\{\frac{1}{2}\frac{1}{2}0\}$ and $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ reflections, respectively. The expected separation of the peak positions between the $\{\frac{1}{2}\frac{1}{2}0\}$ and the $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ reflections is 0.7°, which is beyond our resolution limit. A calculation assuming the presence of both the $\{\frac{1}{2}\frac{1}{2}0\}$ type and the $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ type of reflections gives excellent agreement for the peak positions and widths consistent with the instrumental resolution. The results of this calculation are

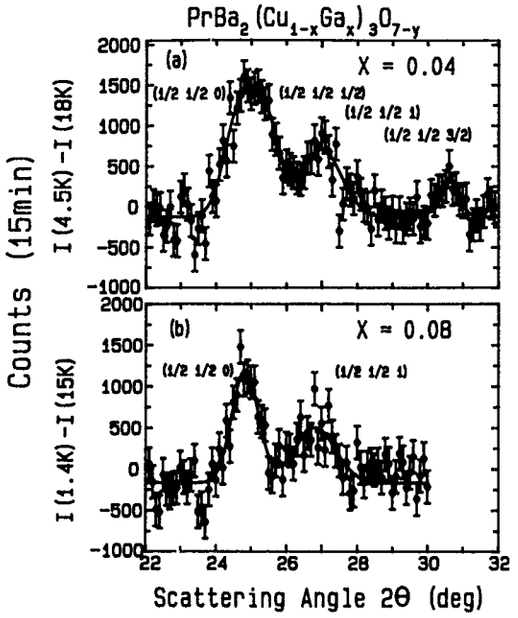

FIG. 1. Magnetic intensities in $PrBa_2(Cu_xGa_{1-x})_3O_7$ with (a) $x=0.04$ at $T=4.5$ K and (b) $x=0.08$ at $T=1.36$ K. Both the $\{\frac{1}{2}\frac{1}{2}0\}$ type and the $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ type of reflections were observed in the $x=0.04$ compound, while only the $\{\frac{1}{2}\frac{1}{2}0\}$ type appeared in the $x=0.08$ compound.

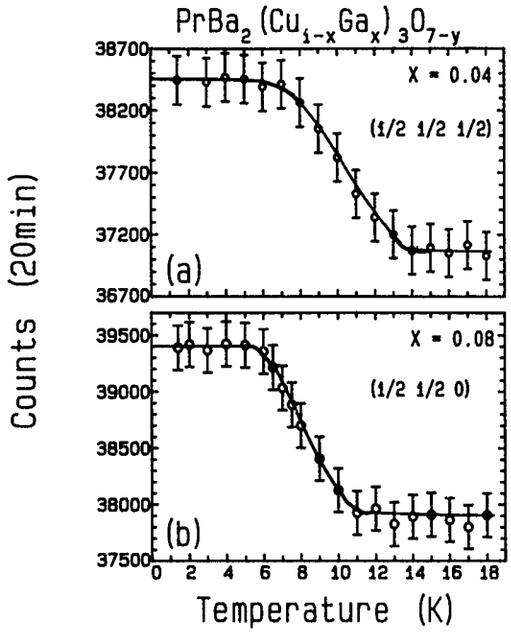

FIG. 2. Temperature dependence of the magnetic peak intensity The Neel temperatures are determined to be 14 and 10 K for the $x=0.04$ and 0.08 compounds, respectively. These data clearly show that the Ga doping effectively reduces the ordering temperature of the Pr spins.

shown as the solid lines in Fig. 1(a). No $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ type of reflections were observed in the data shown in Fig. 1(b), and the solid lines are fits based on the presence of only the $\{\frac{1}{2}\frac{1}{2}0\}$ type of reflections.

The corresponding magnetic structure for the $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ wave vector is that the spins are aligned antiparallel along all three crystallographic directions, and that for the $\{\frac{1}{2}\frac{1}{2}0\}$ wave vector is that nearest-neighbor spins along the c axis aligned parallel rather than antiparallel. Only the $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ type of reflections was observed in the undoped system.[3,9] The observations shown in Fig. 1 then indicate that introducing Ga atoms into $PrBa_2Cu_3O_7$ causes the Pr spins along the c axis to change from antiparallel to parallel. A 12 at. % replacement of the Cu atoms located in the CuO-chain layers by Ga atoms partially reverses the Pr spins arrangement along the c axis, and a 24 at. % replacement complete this reverse.

The temperature dependence of the $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ peak intensity of the $x=0.04$ compound is shown in Fig. 2(a), while that of the $\{\frac{1}{2}\frac{1}{2}0\}$ reflection of the $x=0.08$ compound is shown in Fig. 2(b). Both plots reveal a typical order parameter, that measures the square of the magnetization, for powder samples. The ordering temperatures determined from the data shown in Fig. 2 give $T_N \approx 14$ and 10 K for the $x=0.04$ and 0.08 compounds, respectively. We note that the T_N for the undoped system is 17 K. It is then clear that the ordering temperature of Pr is quite sensitive to the presence of Ga atoms.

The ordered moment can be obtained from a comparison of the magnetic intensities to the nuclear ones, while the spin direction was determined from the relative intensities of the magnetic reflections.[5] The saturated moment that we obtained for the $x=0.08$ compound using the data collected at $T=1.36$ K is $\langle \mu_z \rangle = 0.76 \pm 0.07 \mu_B$ with the moment directed along the c axis. This value of the ordered moment and the spin direction are the same as that found in the undoped system. Thus the Ga atoms do not alter the spin direction or the size of the ordered moment. Based on these results, the percentage in which the spin arrangement along the c axis has been reversed can be estimated by comparing the observed intensities between the $\{\frac{1}{2}\frac{1}{2}0\}$ type and the $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ type of reflections. A calculation using the $\{\frac{1}{2}\frac{1}{2}0\}$ and $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ intensities observed in the $x=0.04$ compound indicates that 80% of the sample has its Pr spins aligned parallel along the c axis. A calculation using the $\{\frac{1}{2}\frac{1}{2}1\}$ and $\{\frac{1}{2}\frac{1}{2}\frac{3}{2}\}$ reflections gives the same value.

The ac susceptibility was measured using the Lake Shore 7221 ac susceptometer. Portions of the real part of the measured ac susceptibility for both compounds are shown in Fig. 3. These data were taken with an alternating magnetic field of strength 3 Oe and frequency 300 Hz; data collected with a frequency as high as 10^4 Hz generated the same results. Above the Neel temperature of Pr, the data follow a Curie–Weiss law very well all the way up to the highest temperature studied of $T=320$ K. However, a small temperature-independent term χ_0 is also needed in describing the data. The solid lines shown in Fig. 3 are obtained by fitting the data to $\chi_0 + C/(T+\theta)$ for 30 K$<T<$320 K. The effects of the Pr ordering on the ac susceptibility are clearly seen. At low temperatures the data deviate from the fitted Curie–Weiss curves, and the temperatures at which these deviations begin agree very well with the T_N of Pr observed using neutron diffraction. However, no cusp on the χ_{ac}-T curve, typical of antiferromagnetic ordering, is observed.

The effective moment μ_{eff} that we obtained using the fitted values for the Curie–Weiss constants C are 3.39 and

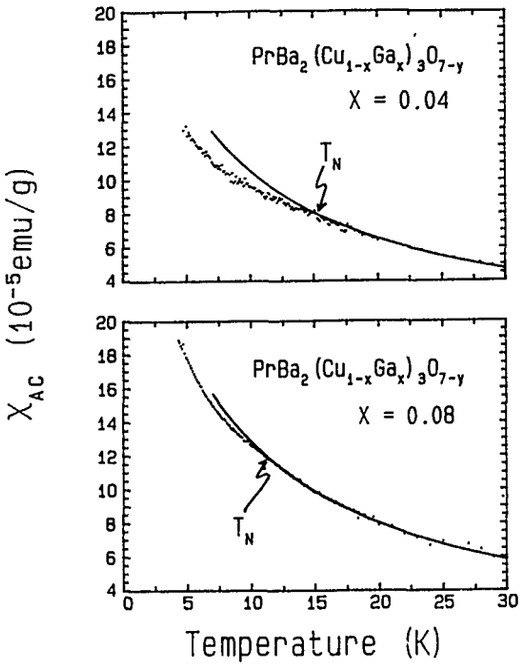

FIG. 3 Portions of the measured ac susceptibility as a function of temperature. The solid lines shown are fitted Curie–Weiss curves using data collected in the temperature range of 30 K<T<320 K. Departures from the fitted curves at low temperatures are clearly seen. The temperatures at which the departures begin match very well to the Neel temperature determined using neutron diffraction.

$3.01\mu_B$ for the x=0.04 and 0.08 compounds, respectively. These values are smaller than the value of $3.58\mu_B$ expected for free ions. We believe that the reduction of the effective moment is likely due to the crystalline electric field effects. As the Ga doping is increased the effect becomes more pronounced and hence the effective moment is much reduced.

In conclusion, the ordering temperature of the Pr spins is effectively reduced by Ga doping, while it is not affected by Zn doping.[4] The Ga atoms substitute into the CuO-chain layers, and the Zn atoms into the CuO_2-plane layers. It is then clear that the CuO-chain layers are more responsible than the CuO_2-plane layers for the high ordering temperature of Pr observed in $PrBa_2Cu_3O_7$.

Galvanomagnetic properties of quasi-one-dimensional superconductors

K. Yu. Arutyunov and N. P. Danilova
Low Temperature Department, Physics Faculty, Moscow State University, Moscow 119899, Russia

A. A. Nikolaeva
Applied Physics Institute of Moldovian Academy of Sciences, Kishinev 277028, Moldovia

The transport properties of thin single-crystalline tin and indium filaments in glass cover were studied. The length of the samples was much greater than the quasiparticle relaxation length. The width of the resistive transition and the electron free path of the samples studied were comparable with the corresponding values of the perfect whiskers. The observed step-like current-voltage characteristic could be described by the model of noninteracting phase-slip centers.

I. INTRODUCTION

The sudden destruction of superconductivity by the transport current of a homogeneous bulk sample could be described by the model of a spreading "hot spot" when the normal phase nucleates within the region of reduced superconducting parameters. It is not obvious whether the above model could be applied to a homogeneous one-dimensional filament. A sample could be considered as a quasi-one-dimensional superconductor with a uniform current flowing in if the coherence length $\xi(T)$ and the field penetration depth $\lambda(T)$ are not small compared to the transverse dimensions. Due to strong temperature dependences of $\xi(T)$ and $\lambda(T)$ the requirement of quasi-one-dimensionality for clean I-type superconductors holds within few mK below T_c for the samples of several microns in diameter.

For small measuring currents the resistive transition curves $V(T)$ for thin whiskers is very small (~1 mK) and show the typical smooth shape of a fluctuation governed phase transition.[1] However, for high measuring currents the transition width rises and the voltage steps build up which become more distinct for larger fixed currents.[2] The voltage steps are also observed in the $V(I)$ characteristics at fixed temperatures few mK below the critical temperature T_c.[2]

At the present moment we may state that the step-like peculiarities of the voltage-current characteristics in quasi-one-dimensional superconductors could be qualitatively described by the essentially nonequilibrium process of the phase-slip centers (PSC) activation.[3] Still there are some questions which are not clear enough. One of them is the problem of the interaction of the PSC on a distances comparable with the length of quasiparticle charge imbalance relaxation.

In the present work we present the experimental study of galvanomagnetic properties of long tin and indium filaments in a glass cover. The process of filament drawing permits us to produce a homogeneous wire of hundred meters in length with highly uniform parameters. However, the existence of the glass cover along with considerable reinforcement of the metal core initiates several problems with the partial removal of the glass for voltage and current probes. That is why in the present work special attention is paid to contact effects.

II. EXPERIMENT

The filaments were prepared by drawing of molten metal in glass capillary.[4] Depending upon the metal, type of the glass, temperature, cooling, and speed of the wire spinning it is possible to produce filaments with diameter of metal core from 0.6 to 40 μm. X-ray analysis showed that all the wires studied are single crystals. The observation of the samples with the scanning electron microscope (SEM) displayed no cuts.

The filament with length ~1 cm was glued to a sapphire substrate excluding narrow ~20 μm regions for electrodes where the glass was removed with hydrofluoric acid. The current probes were prepared by direct placing silver paint or Wood's metal above the glass-free ends of the filament. The best results for potential probes were obtained by placing a 8 μm copper wire covered with a thin layer of conducting epoxy across the sample.

The samples were mounted inside a massive vacuum calorimeter with an internal heater. The temperature was stabilized with a double-level PID controller system with an accuracy ± 0.1 mK. All measurements were performed using a conventional four-probe method. External magnetic field was generated with a double-layer solenoid. The Earth magnetic field was reduced to ≤ 1 mOe by the superconducting shield.

III. THEORY

Soon after the experimental observation of a step-like $V(I)$ structure of tin whiskers[2] Scocpol, Beasley, and Tinkham (SBT) proposed a model[3] which can qualitatively describe the observed phenomena. The SBT model associates the voltage steps with activation of PSC along the one-dimensional superconductor. The PSC is a region of weakened superconductivity (S-S'-S boundary). The idea of PSC is related with the assumption that the phase $\varphi(r,t)$ of the superconducting order parameter $\Psi(r,t)=\Psi^2\exp[i\varphi(r,t)]$ is periodically reduced by 2π to compensate the monotonic growth of the time-dependent phase due to the existence of nonzero voltage across the PSC: $d\varphi/dt=2$ eV/h. In order the process could be stationary in time the period of the phase-slip events should be equal to $\tau_{slip}=h/(2e\langle V\rangle)$, where $\langle V\rangle$ is the time-averaged voltage across the PSC.

SBT postulated that the phase-slip event occurs within the range $\sim\xi(T)$ of the PSC core, while the nonequilibrium quasiparticles charge imbalance relax on a length scale $\Lambda=(1/3lv_F\tau_e)^{1/2}$, where l is the mean-free path, v_F the Fermi velocity, and τ_e is the elastic electron relaxation time.

 0021-8979/94/76(10)/7139/3/$6 00 © 1994 American Institute of Physics

The current-voltage characteristic of a single PSC could be described by[3]

$$V(I)=\frac{dV}{dI}(I-I_0), \tag{1}$$

where I_0 is the excess current and the differential resistance (dV/dI) is associated with the resistance of the normal-like section of length $L(1)=2\Lambda$.

Later, Tinkham[5] applied the ideas of SBT to describe the current-voltage characteristics of an ideal homogeneous filament. The resulting step-like $V(I)$ dependence was associated with successive activation of N independent PSC at critical currents $I_c=I_c(1)<I_c(2)<\cdots<I_c(N)$. The interaction of the PSC is reduced to the activation of the successive PSC midway between existing ones. For sufficiently long filament $L/2N\Lambda\gg 1$ the PSC are well separated and weakly interacting. The general spacing of the predicted steps is in a reasonable agreement with experimental results,[6] but the positions of the first steps are separated by inevitable inhomogeneities, which overwhelm the exponentially weak interaction of the ideal model.[5]

Kadin, Smith, and Scocpol (KSS) developed a detailed model of a charge imbalance wave equation for a PSC connected to a transmission line.[7] The KSS model includes the SBT as a limit of a diffusive decay of a charge imbalance. However, KSS showed that under some conditions the relaxation of charge imbalance results in propagating of charge-imbalance waves on the scales much greater than the Λ of the SBT model. Therefore, the KSS model predicts the long-distance interaction of the PSC.

Along with the models involving the phase-slip event[3,7] the generalized time-dependent Ginzburg–Landau (TDGL) model was introduced to describe the transport properties of one-dimensional superconductors.[8]

However, taking into account the inevitable inhomogeneities of the actual superconducting filaments and restricting attention to the first voltage steps of the $V(I)$ transition one can use the SBT model to rationalize the experimental results.

IV. RESULTS AND DISCUSSION

For all the samples studied the relation of resistance at room temperature R(room) to the one at 4.2 K $R(4.2)$ is used for calculation of the mean-free path l utilizing the well-known values for the product (ρl) and ρ(room) for tin and indium.[6] It was found that the mean-free path l monotonically increase with increasing of the filament diameter, reaching the maximum value of $l=6$ μm for 8 μm indium filament and $l=3.4$ μm for the thick 13 μm tin wire.

The width of the superconducting resistive transition ΔT_c varies from 0.01 to 0.15 K. Measuring the samples prepared from different parts of the same filament it was found that the broadening of the resistive transition is greatly determined by the quality of the contacts. An example of the wide resistive transition is shown in Fig. 1 for indium sample In-F1. It is clearly seen that there are at least two kinks on the $R(T)$ dependences at $H=0$. The form of the transition depends upon the direction of the temperature variation, displaying small hysteresis even for zero magnetic field. The kinks are related to the existence of weakened superconductivity in the locus of the potential probes. Joule heating leads to a small hysteresis. The application of the external magnetic field $H<H_c^{\text{bulk}}$ may efficiently suppress the weak superconductivity resulting in smooth $R(T)$ dependences at least at a high-temperature region. We suppose that the increase of number of kinks at a low-temperature limit is due to the generation of the intermediate state in the weakened region by the magnetic field. The suppression of superconductivity in the locus of contacts is a reversible process. Careful remounting of potential probes of the same sample may significantly smooth out the form and decrease the width ΔT_c of the resistive transition.

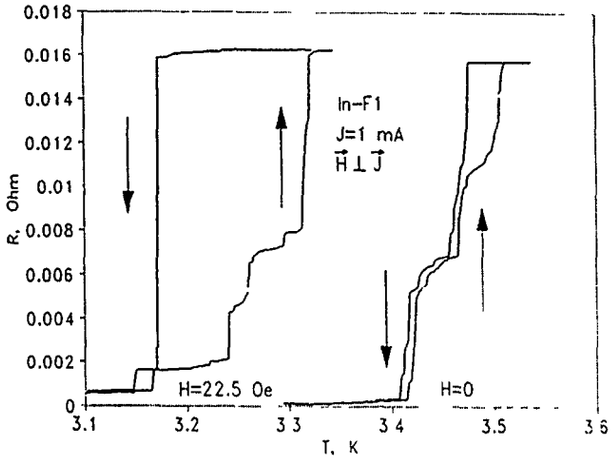

FIG. 1. Resistance vs temperature for the sample In-F1 for zero magnetic field and for applied transverse (H⊥J) magnetic field $H=22.5$ Oe. Arrows indicate the direction of the temperature variation.

However, along with the discussed above "contact" broadening of the $R(T)$ dependences, the increasing of measuring current increases the width of the resistive transition ΔT_c, displaying a step-like structure and hysteresis. We suppose that the observed phenomenon is related not only with the inevitable thermal heating,[9] but also with the details of nonequilibrium quasiparticle relaxation.[7]

The voltage-current characteristics at fixed temperatures display a wide transition with pronounced step-like structure (Fig. 2). Each $V(I)$ curve could be approximated by a set of voltage jumps $V(i)$ at currents $I_c(i)$ and linear plateaus with "constant" differential resistance $(dV/dI)_i$. The finite curvature of the actual $V(I)$ characteristics indicates the existence of heating. As one may expect, because of the existence of the glass cover, the heating effects are observable, but not so significant to smear out the step-like structure of the $V(I)$ transitions.

According to the model of noninteracting PSC[5] the increments of differential resistance for all voltage steps are equal: $(dV/dI)_i-(dV/dI)_{i-1}=(dV/dI)_1=\text{const}$. Due to the heating effects mentioned above, we cannot state that the above relation holds for all steps of $V(I)$ transition. But from Fig. 2 it can be clearly seen that $(dV/dI)_i$ increases with an increase of the transport current I.

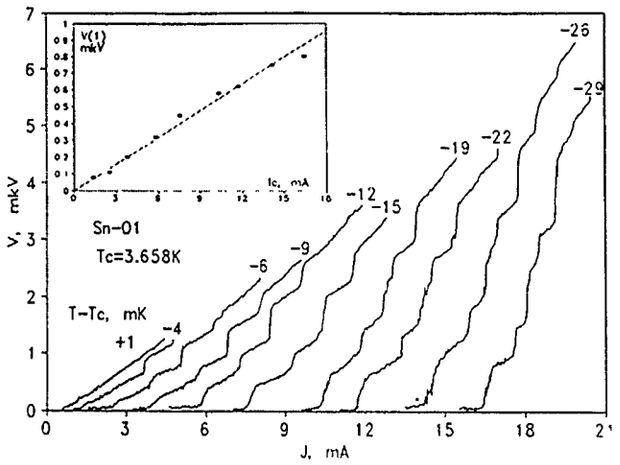

FIG. 2. Voltage-current characteristics of the sample Sn-O1 for fixed temperatures $\Delta T = T - T_c$. The inset shows the amplitude of the first voltage step $V(1)$ as a function of the critical current $I_c(1)$.

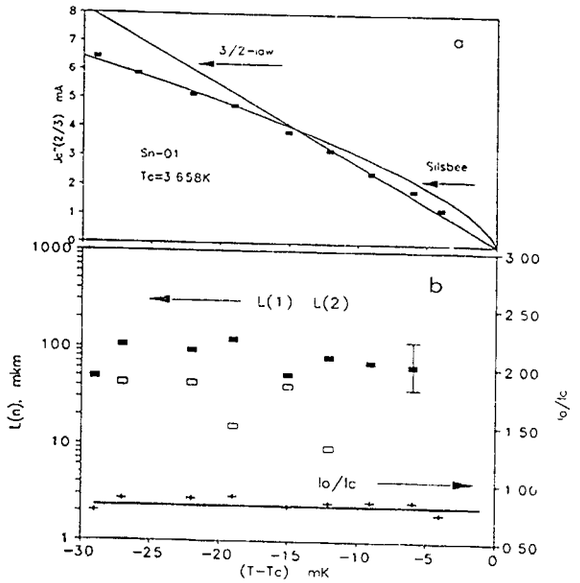

FIG. 3. (a) Critical current $I_c(1)^{2/3}$ as a function of the temperature $\Delta T = T - T_c$ for the sample Sn-O1. The lines are the theoretical calculations: the "3/2" law $I_c \sim (T_c - T)^{3/2}$ and the Silsbee rule $I_c \sim (T_c - T)^2$. (b) Relation I_0/I_c (+) and the normal-like lengths $L(1)$ (■), $L(2)$ (□) vs temperature $\Delta T = T - T_c$ for the sample Sn-O1. The solid line corresponds to the value $I_0/I_c = 0.8$

In the SBT model,[3] the quasilinear plateaus of the $V(I)$ transition are associated with activation of PSC with normal-like lengths $L(i) = 2\Lambda$:

$$L(i) = [(dV/dI)_i - (dV/dI)_{i-1}](L/R_N), \qquad (2)$$

where L is the length of the sample and R_N the normal resistance. Figure 3(b) shows the temperature dependences of $L(1)$ and $L(2)$ corresponding to $V(I)$ transition of Fig. 2. Significant dispersion of $L(i)$ experimental values is related with the problem of $(dV/dI)_i$ correct definition of the actually curved $V(I)$ plateaus. Within experimental errors no temperature dependence could be observed. The absence of temperature dependence and the values $L(i,T)$ correlate well with existing results for tin whiskers.[6]

It is remarkable that the height of the first voltage jump $V(1) = V[I_c(1)]$ follows a straight line (Fig. 2, inset), which holds for all tin and indium samples. Since according to Eq. (1), $V(1) = (dV/dI)_1[1 - I_0/I_c(1)]I_c(1)$ this observation indicates that the temperature dependence of $(dV/dI)_1$ and $[1 - I_0/I_c(1)]$ compensate each other so that their product is independent of the temperature and, therefore, is constant for different critical currents $I_c(1,T)$.

According to the SBT model[3] the relation of excess current to the critical value is a constant equal to $I_0/I_c \approx 0.6$. Within experimental errors our results give the value $I_0/I_c \approx 0.8$ for the first step [Fig. 3(b), right axis] which correlate with the TDGL model.[8]

The temperature dependence of the critical current $I_c(1,T)$ at temperatures close to critical value T_c follows the "3/2" law for a one-dimensional filament: $I_c(T) \sim (T_c - T)^{3/2}$ [Fig. 3(a)]. For low enough temperatures there are deviations from the "3/2" law and the $I_c(T)$ follows the Silsbee rule for a three-dimensional superconductor [Fig. 3(a)]. It is remarkable that, nevertheless, the sample displays qualitatively the same step-like $V(I)$ transition at low temperatures ($T_c - T \geq 20$ mK) being not one-dimensional (Fig. 2). The low-temperature behavior of superconducting filaments is a subject for future investigations.[10]

Remanent magnetization of layered and isotropic superconductors (abstract)

Yu. V. Bugoslavsky, A. A. Minakov, and S. I. Vasyurin
General Physics Institute 117942, Vavilov st. 38, Moscow, Russia

There are contradicting data on the anisotropy of remanent magnetization of high-temperature superconductors.[1-3] To clarify the mechanism of this anisotropy we performed a comparative study of thermoremanent (TRM) and isothermal remanent (IRM) magnetizations. We report on the results obtained on layered single crystals of LaCrSuO and RBaCuO (R=Y,Gd) families as well as on isotropic soft alloy Bi:Pb:Sn and nontextured ceramic YBaCuO samples. The experiments were done by means of a vibrating-sample magnetometer. The external magnetic field up to 8 kOe was applied to magnetize the samples at arbitrary directions. It was found that all the studied plate-like samples show the effect of "easy remanent magnetization axis:" the vectors of IRM and TRM tend to point along the normal of the plate at any magnetizing or cooling angle. In the case of TRM this effect can be well described considering the influence of the sample shape. This fact was proved by measurements on samples with substantially different aspect ratios. Thus, we argue that the anisotropy of TRM is not related to anisotropic flux trapping. The anisotropy of IRM is a more complex phenomenon, as it involves inhomogeneous flux distribution in the sample. Nevertheless, it was found that the dependence of IRM direction on the magnetizing angle is also governed mainly by the sample shape. The corrections to the effective demagnetization factors were calculated, which arise due to the flux distribution. The analysis of the absolute value of IRM on the magnetizing angle allows one to distinguish between the influence of the critical current anisotropy and the sample shape.

Two types of additional maxima in magnetization curves of layered superconductors (abstract)

Yu. V. Bugoslavsky and A. A. Minakov
General Physics Institute, 117942 Vavilov St. 38, Moscow, Russia

We report on magnetic measurements of LaSrCuO and YBaCuO single crystals in order to clear up their anomalous behavior and to attribute it to the crystals' anisotropic properties. Magnetization curves were obtained by means of a vibrating sample magnetometer at temperatures from 4.2 to 90 K. The magnetic field up to 8 kOe was applied at various angles with respect to the crystal c axis. Our main findings are that there are two physically different types of additional maxima, as ruled out from the evolution of magnetization curves with varying the tilt angle of the external field. One type of the maxima is attributed to anisotropic flux penetration into a sample and flux-line-lattice rotation with increasing the field. We provide an experimental justification of this explanation. The second type of maxima is related to an anomalous increase of the critical current in magnetic field which is often referred to as the "fishtail" phenomenon. It was found that the existence of the fishtail is closely related to the anisotropy of flux pinning. On this basis a qualitative model was developed to describe this phenomenon. The model takes into account vortex interaction with stretched pinning sites and the vortex bending due to stray fields in the sample. The formation of staircase flux lines is also assumed, as specific for layered superconductors. The qualitative explanation of the fishtail is as follows. At low fields the flux lines are strongly curved. When increasing the field, they straighten and fit the linear pinning sites better, which gives rise to more effective flux line fixing. The proposed model allows to describe the angular and temperature dependencies of the additional maximum position.

"Effective radius" of the 4*f* electrons in $REBa_2Cu_3O_7$, RE=Dy, Ho, Er (abstract)

Yu. A. Koksharov and P. K. Silaev
Department of Physics, Moscow State University, Moscow 119899, Russia

It is well known that in most high-temperature superconductors rare earth (RE) ions and superconducting copper-oxygen planes coexist as rather isolated subsystems. It would be expected that the "magnetic" $4f$ electrons are to be strongly localized as it takes place in many oxides.[1] On the other hand, significant crystal-field (CF) splitting of RE ground states is evidence that the "effective radius" of the $4f$ electron wave functions (WF) could be large.[2–4] This matter could be responsible for the disappearance of the superconductivity in Pr_{123} since the "effective radius" of the $4f$ electron WF increases from Yb to Ce. There is the adequate complete information about CF splitting in $HoBa_2Cu_3O_7$ (Ho_{123}) from inelastic neutron scattering experiments. The energies of low-lying levels are known also for Dy_{123}[3,4] and Er_{123}.[3] To compute CF splitting in RE_{123} compounds the hydrogen-like one-electron radial WF $R(r)=(rN)\exp(-alpha\ r)$ are used. Only five parameters are taken into account to accord the calculated and experimental data: alpha, N, and effective charges of nearest oxygen, copper, and barium ions. The minimal discrepancy for Ho_{123} is small enough for such simple approximation. The minimum is observed with enough magnitude of alpha than the one in the case of free Ho_{3+} ion. The same is true for Dy_{123} and Er_{123}. This fact points out the strong localization of the $4f$ one-electron radial wave function and probably on the small covalent mixture of $4f$ ("magnetic") and $3d$-$2p$ ("superconducting") orbitals.

Helicoidal, magnetic vortex in a current-carrying superconductor in a longitudinal magnetic field: New exact solution (abstract)

Yuri A. Genenko
Donetsk Phystech, 340114 Donetsk, Ukraine

A resistive state in a type-II superconductor (SC) is conditioned by the Abrikosov magnetic vortex motion in them. In absence of external magnetic field the entry of vortex rings of a transport current self field determines the resistivity oneset.[1] Being applied along the current-carrying SC cylinder the magnetic field does not affect the entry of self-field vortex loops, because of force-free geometry.[2] In a latter case other vortex configurations, more likewise a field line pattern, seem to face less edge barrier against vortex entry and determine the resistivity onset. In this work an exact solution for helicoidal magnetic vortex is found in a London approximation, similar to magnetic helicoidal configurations known in magnetism. The Gibbs free energy of the current-carrying SC cylinder in a parallel magnetic field is constructed and the edge barrier problem of irreversible entry of helicoid into the SC sample is solved. An optimal parameter of helicoid is chosen by minimization of critical SC parameters (current or field) for vortex entry. The phase diagram of resistive state in coordinates current field is evaluated. An essential difference of magnetic behavior between thin (of radius $R<1$, London penetration depth) and thick ($R\gg1$) samples is shown. The latter exhibit the field-dependent critical current J_{cr} due to the helicoid entry in almost all of the field region $H<H_c$, the thermodynamic critical field, while for $R<1$ J_{cr}, almost field-independent, is determined by the vortex ring entry.

Ga substitution effect on magnetic and magnetostrictive properties of $TbFe_2$ compounds

Y. J. Tang, Y. B. Feng, and H. L. Luo
Institute of Physics, Academia Sinica, Beijing 100080, People's Republic of China

S. M. Pan
General Research Institute for Non-Ferrous Metals, CNNC, Beijing 100088, People's Republic of China

In the present paper magnetic and magnetostrictive properties of $Tb(Fe_{1-x}Ga_x)_2$ ($x=0-0.2$) compounds were investigated. It was found that the iron moment of the compounds does not seem to vary much for $x\leqslant 0.12$. The Curie temperatures of the compounds decrease continuously by substituting Ga for Fe, which was attributed to the decrease of the R-T coupling strength due to Ga substitution. The intersublattice coupling constant J_{RFe} was evaluated by molecular field model. The decrease of J_{RFe} with increasing Ga content was found and related to the decrease of the number of the Tb-Fe interaction pairs when replacing Fe with Ga. By using an x-ray diffractometer the samples were step scanned with Cu radiation at a higher Bragg angle 2θ ranging from 71° to 74° to study the cubic (440) reflection. The splitting of (440) reflection for $X\leqslant 1.2$ was clearly seen and the easy direction magnetostriction λ_{111} of the compounds was calculated. It was found that λ_{111} decreases with increasing Ga content. This was attributed to the decrease of magnetic properties of the compounds. The polycrystal magnetostriction λ_s of the compounds has also been studied.

I. INTRODUCTION

Substitution of Fe with other transition metals, such as Mn, Co, Ni, Al, etc., in RFe_2 cubic Laves compounds are of considerable interest because in some cases such substitution can improve the magnetostriction of the compounds.[1–4] According to Clark *et al.*[5] the magnetostriction of such compounds are highly anisotropic, exhibiting different magnetostrictive characters depending on their easy magnetization direction, i.e., $\lambda_{111}\gg\lambda_{100}$. The huge λ_{111}'s are allowed because two inequivalent tetrahedral rare earth sites exist in the C15 structure while the potentially huge values of λ_{100} are shorted out because of the high tetrahedral symmetry at the rare earth site, which means that only transition metal contributes to λ_{100}. It was found[2] that the magnetostriction of $Tb_{0.3}Dy_{0.7}(Fe_{1-x}T_x)_2$ decreases when replacing Fe with Ni or Co. Teter *et al.*[3] also found that the low Tb concentration samples with Mn substitution do show a tendency to have a lower $\Delta H/\lambda$ ratio than the pure iron ones in a twinned single crystal of Mn substituted Terfenol-D. Recent studies[1,6] have found that substituting Fe with Mn in $Tb_xDy_{1-x}Fe_2$ compounds could shift the magnetocrystalline anisotropy compensation composition to higher Tb content and was effective to improve their magnetostriction because of the Mn influence on the magnetocrystalline anisotropy; and Mn substitution in $DyFe_2$ increases the magnetostriction at room temperature, especially in low fields, which is suggested to be caused by λ_{100} increase. It was also found[7] that the magnetostriction shows a significant increase with substituting a small amount of Mn in $Y_{0.1}Tb_{0.9}(Fe_{1-x}Mn_x)_2$ compounds. These results suggested that transition metals could play a relative important role in improving the magnetostriction of RFe_2 compounds through R-T interaction, especially at low fields.

Although the theory of anisotropy and magnetostriction is well developed for the rare-earth sublattice in RFe_2 Laves compounds, a detailed understanding of the effect of the transition metals on magnetostriction proved to be elusive. A better knowledge of such an effect both from experimental and theoretical points of view may lead to some discoveries of new giant magnetostrictive materials at relatively low field.

In the present study magnetic and magnetostrictive properties of $Tb(Fe_{1-x}Ga_x)_2$ ($x=0-0.2$) compounds were measured in order to reveal the substitution effect.

II. EXPERIMENT

The $Tb(Fe_{1-x}Ga_x)_2$ ($x=0-0.2$) compounds were arc melted in a magnetocontrolled arc furnace under an atmosphere of very pure argon, and annealed at 900 °C for a week under a purified-argon atmosphere. X-ray analysis showed that all samples were single phase of cubic Laves structure (C15). Curie temperature was obtained by extrapolating the σ^2-T curve to $\sigma^2=0$. Saturation magnetization (σ_s) was measured in the extraction magnetometer with field up to 60 kOe at 1.5 K. Polycrystal magnetostriction λ_s was measured by using the strain gauge method in applied field up to 20 kOe at room temperature and was obtained by using parallel strain $\lambda_\parallel$ and perpendicular strain $\lambda_\perp$, to applied magnetic field as follows:

$$\lambda_s=\tfrac{2}{3}(\lambda_\parallel-\lambda_\perp). \tag{1}$$

TABLE I. Lattice constant a, Curie temperature T_c, and intersublattice coupling constant J_{RFe} for $Tb(Fe_{1-x}Ga_x)_2$ compounds. The values $Z_{RFe}=12$, $Z_{FeR}=6$, $S_{Fe}=0.78$, $g_R=3/2$, and $J=6$ are used in the calculation.

X	a (Å)	T_c (K)	$-J_{RFe}$ (10^{-22} J)
0	7.346	694	2.1
0.03	7.360	662	1.6
0.06	7.370	614	0.9
0.09	7.383	593	0.6
0.12	7.391	545	0.3

By using an x-ray diffractometer, the samples in powder form were step scanned with Cu radiation at a higher Bragg angle 2θ ranging from 71° to 74° in order to study the cubic (440) reflection. The absolute error of the measurement for the lattice constant is less than 0.002 Å. The easy direction magnetostriction λ_{111} of the compounds was calculated by:[8]

$$\lambda_{111}=\Delta\alpha, \tag{2}$$

where $\Delta\alpha$ is the deviation of the angle between neighboring edges of the distorted cube from $\pi/2$.

III. RESULTS AND DISCUSSION

The lattice constants of $Tb(Fe_{1-x}Ga_x)_2$ ($x=0-0.12$) compounds were measured by x-ray diffraction and listed in Table I. It could be found that they increase with increasing Ga content, obeying Vegard's law. Studying the magnetic behavior of $TbFe_2$ compounds both as a single crystal and polycrystal from previous research,[5] we found that even at 120 kOe it was impossible to saturate the polycrystal samples at 4.2 K. In the present study, the polycrystal moment is reduced by about 10% below the single-crystal value. Assuming the same reduction of the moment for $Tb(Fe_{1-x}Ga_x)_2$ compounds, we obtained from the saturation data an iron magnetic contribution $(1.56\pm0.03)\mu_B$ for the entire concentration range.

Although the iron moment does not seem to vary much in the studied composition range, the Curie temperatures T_c of $Tb(Fe_{1-x}Ga_x)_2$ compounds decrease continuously by substituting Ga for Fe. This is evidence that the greatest contribution to T_c values is given by the interactions involving the iron atoms. T_c reduction can be attributed to the decrease of the R-T coupling strength due to Ga substitution. On the basis of molecular field theory the R-T intersublattice-coupling constant J_{RFe} can be obtained by:[9]

$$(J_{RFe}/k)^2=\frac{9(T_C-T_C^Y)T_C}{4Z_{RFe}Z_{FeR}S_{Fe}(S_{Fe}+1)(g_R-1)^2J(J+1)}, \tag{3}$$

where T_c and T_c^Y represent the Curie temperatures of the compounds in which R is magnetic ($J\neq0$) or R is nonmagnetic ($J=0$), respectively; k is Boltzmann constant. Some parameters used in the calculation are listed in Table I. Here YFe_2 was used as the $J=0$ compound in the calculation. The magnetic-coupling strength constants derived from Eq. (3) are listed in Table I. For $TbFe_2$, J_{RFe} is 2.1×10^{-22} J, which agrees well with $153k$ (yields a value of 2.3×10^{-22} J) estimated from Mössbauer spectra for RFe_2 compounds[10] and somewhat smaller than 19.1 K for J_{RFe}/k (yields a value of 2.6×10^{-22} J) derived from high field measurements,[9] and 2.93×10^{-22} J evaluated by *ab initio* calculations.[11] The decrease of J_{RFe} with increasing Ga content is apparently seen from Table I. This can be related to the decrease of the number of the Tb-Fe interaction pairs when replacing Fe with Ga.

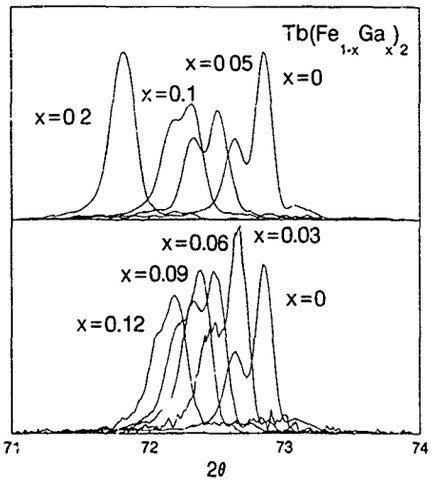

FIG. 1. X-ray spectra for $Tb(Fe_{1-x}Ga_x)_2$ compounds

$TbFe_2$, whose easy direction is parallel to [111], presents a rhombohedral distortion at room temperature. We suppose that no easy direction change occurs for the entire concentration range for $Tb(Fe_{1-x}Ga_x)_2$ ($x=0-0.2$) compounds. In this study λ_{111} was determined from the splitting of the high Bragg angle (440) reflection. The splitting of the (440) reflection due to the distortion is of the same order of magnitude as the one due to the doublet $K\alpha_1$, $K\alpha_2$; actually a triplet is observed. So the reflection created by $K\alpha_2$ is deducted from the whole reflection using a standard method. Figure 1 shows the x-ray spectra after deduction for the compounds. For $TbFe_2$, the calculated distortion is 0.0024, which corresponds to a rhombohedral angle $\alpha_R=89.86°$. This result shows a good agreement with single crystal data[5] and

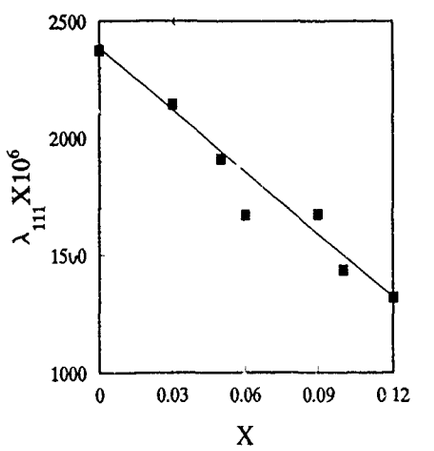

FIG 2. Ga concentration dependence of λ_{111} for $Tb(Fe_{1-x}Ga_x)_2$ compounds

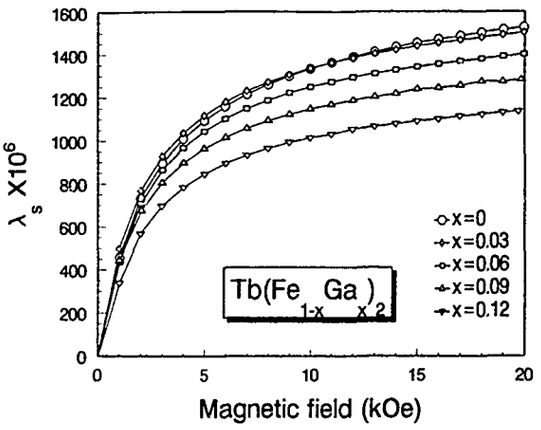

FIG. 3. Magnetic field dependence of polycrystal magnetostriction for $Tb(Fe_{1-x}Ga_x)_2$ compounds.

previous x-ray studies for $TbFe_2$.[12] The splitting of the (440) reflection is clearly seen from Fig. 1. It decreases with increasing Ga content. When $X=0.2$ the splitting disappears, which means that the distortion becomes too small to be measured at room temperature. It could also be found from Fig. 2 that λ_{111} decreases linearly with increasing Ga content, which can be attributed to the decrease of magnetic properties of the compounds. It is well known that the large magnetostriction in RFe_2 compounds is due to the interactions of the anisotropic cloud of the $4f$ electrons with the crystal field and transition metals. According to the single-ion model, the magnetostriction varies with temperature as $\sigma_R^3(T)$. Assuming that the R sublattice moments decrease with decreasing Curie temperature, the rapid decrease in T_c with increasing Ga content results in a strong decrease of $\sigma_R(T)$ at room temperature, which in return leads to a marked reduction in magnetostriction. Figure 3 shows the polycrystal magnetostriction λ_s versus applied magnetic field at room temperature for the compounds. It can be seen that the magnetostriction of the compounds are not saturated even at 20 kOe. We note that the magnetostriction at 20 kOe drops with increasing Ga content. This situation is not the same as that for $Y_{0.1}Tb_{0.9}(Fe_{1-x}Mn_x)_2$ compounds in which the magnetostriction shows a significant increase with a small amount of Mn compounds.[7] This suggests that substitution Ga cannot improve the saturated magnetostriction for $TbFe_2$ compound.

IV. CONCLUSION

In conclusion we would like to point out that:

(1) while the iron moment does not seem to vary much in the studied composition range for $Tb(Fe_{1-x}Ga_x)_2$ ($x=0-0.12$) compounds, the Curie temperatures T_c decrease continuously by substituting Ga for Fe, which was attributed to the decrease of the R-T coupling strength due to Ga substitution. The decrease of J_{RFe} with increasing Ga content, which was obtained by molecular field model, can be related to the decrease of the number of the Tb-Fe interaction pairs when replacing Fe with Ga.

(2) The splitting of (440) reflection for $x \leq 1.2$ was clearly seen and the easy direction magnetostriction λ_{111} of the compounds was calculated. It was found that λ_{111} decreases with increasing Ga content, which was attributed to the decrease of magnetic properties of the compounds. By using the strain gauge method, we found that substitutional Ga cannot improve the polycrystal magnetostriction for the $TbFe_2$ compound.

Comparison of the dynamic magnetomechanical properties of $Tb_{0.27}Dy_{0.73}Fe_2$ and $Tb_{0.30}Dy_{0.70}Fe_2$

D. Kendall[a] and A. R. Piercy
Department of Mathematical Sciences, University of Brighton, Brighton BN2 4GJ, United Kingdom

Comparison is made between the magnetomechanical properties of $Tb_{0.27}Dy_{0.73}Fe_2$ (27 Tb) and $Tb_{0.30}Dy_{0.70}Fe_2$ (30 Tb), two commercially available compositions of the giant magnetostrictive alloy Terfenol-D. The quasi-static magnetostriction (as a function of bias field) and the dynamic strain coefficient (as a function of bias field and frequency) are shown for the two compositions at room temperature, using stress bias values of 0 and 9 MPa. The energy loss per cycle as a function of frequency is also given. The data for the static magnetostriction versus bias field shows 30 Tb to exhibit a significantly greater increase in initial slope and saturation strain when stress bias is applied compared to that seen for 27 Tb, which possesses superior magnetostriction at zero stress bias. A similar trend is observed in the data for the dynamic strain coefficient with 30 Tb again performing better under stress bias. The widening of the static strain hysteresis loop observed for stressed 30 Tb is seen to manifest itself in the low frequency energy loss per cycle; however 27 Tb is observed to possess the higher eddy current loss at 1 kHz. Data for the ratio d/χ, a quantity which is dependent only on magnetization processes and material constants, are shown which suggests that the application of a stress bias affects the magnetization processes, but differently for the two compositions.

INTRODUCTION

The magnetomechanical properties of Terfenol-D of nominal composition $Tb_{0.27}Dy_{0.73}Fe_2$ have been extensively investigated for use in actuator and transducer devices (see the review by Jiles[1]). It has also been widely reported that the composition $Tb_{0.30}Dy_{0.70}Fe_2$, under stress bias, has a high saturation magnetostriction and a high differential (quasi-static) strain coefficient (the burst effect[2]) making the material suitable for use in actuators, but little has been reported on the dynamic properties and frequency response of this composition. In this article, a comparison is made of the static and dynamic magnetomechanical properties of commercial samples of $Tb_{0.27}Dy_{0.73}Fe_2$ and $Tb_{0.30}Dy_{0.70}Fe_2$, both with and without stress bias.

EXPERIMENT

The magnetomechanical properties of the Terfenol-D samples were determined at room temperature in an electromagnet using a strain gauge to measure the static and dynamic magnetostriction and search coils to monitor the drive field and dynamic magnetization in the material. A drive field of 2 kA m^{-1} rms (5.6 kA m^{-1} peak-to-peak) was employed. The energy loss per cycle per unit volume (W) was calculated from the measured values of the peak drive field, the magnitude of the dynamic relative permeability (μ_{r33}) and the phase of μ_{r33} with respect to the drive field (the loss angle, δ_B).

Stress bias was applied to a sample in the electromagnet using a rig comprising perspex head and tail pieces held together by three bolts. The compressive stress was supplied by a spring on each bolt and the rig was calibrated using a load cell in order subsequently to allow the force to be determined through the number of turns on the bolts. The amount of perspex between the ends of the sample and the pole pieces was kept to a minimum to reduce demagnetizing effects.

Both samples were manufactured by ETREMA of Edge Technologies, Ames, Iowa, and were 6 mm in diameter and cut to a length of 64 mm to fit the stress rig. In this article the sample of composition $Tb_{0.27}Dy_{0.73}Fe_2$ is referred to as 27 Tb and the sample of composition $Tb_{0.30}Dy_{0.70}Fe_2$ as 30 Tb.

RESULTS AND DISCUSSION

The quasi-static magnetostriction as a function of bias field is shown in Fig. 1 for the two Terfenol-D compositions under 0 and 9 MPa stress bias. It is clear from these plots that applying a stress to 30 Tb transforms the material from one that is inferior to 27 Tb with respect to initial slope and high-field magnetostriction to one that is superior. The high

TABLE I. Summary of the magnetomechanical properties of $Tb_{0.27}Dy_{0.73}Fe_2$ and $Tb_{0.30}Dy_{0.70}Fe_2$ at 0 (plain) and 9 MPa (italic) stress bias.

Composition	$d_{33max\ 70\ Hz}$ / nm A^{-1}		H_{d33max} / kA m^{-1}		λ_{sat} / 10^{-6}		W_{hyst} / J m^{-3} $cycle^{-1}$		$W_{eddy\ 1\ kHz}$ / J m^{-3} $cycle^{-1}$	
$Tb_{0.27}Dy_{0.73}Fe_2$	15.3	*10.4*	12.5	*30.0*	1100	*1490*	3.8	*4 0*	7.9	*17.9*
$Tb_{0.30}Dy_{0.70}Fe_2$	10.5	*16.2*	4.5	*22.0*	990	*1840*	3 8	*9.0*	3.8	*12.9*

initial slope for the 30 Tb composition under stress bias has been termed the burst effect[2] and is thought to be due to jumping[3] of the magnetization in a domain from the easy direction perpendicular to the axis of the rod to that closest to this direction. The maximum theoretical saturation strain for a ⟨112⟩ oriented rod of Terfenol-D is approximately 1250×10^{-6} unstressed and 2080×10^{-6} stressed (assuming $\lambda_{111}=1640\times10^{-6}$ and $\lambda_{111}/\lambda_{100}=16$). Values for the saturation strain λ_{sat} obtained by extrapolation against $1/H$, are shown in Table I and it is clear that neither composition has the theoretical value under zero stress. This may be partly attributed to axial misalignment of the Terfenol-D grains although, while the 27 Tb sample is 12% lower than the theoretical value, the 30 Tb composition is almost 21% lower. This behavior is not reflected when stress bias is applied since, although the theoretical maximum has not been reached (a higher stress bias is required[4]), the saturation strain for 30 Tb is 350×10^{-6} greater than that for 27 Tb. If the initial state of magnetization for 30 Tb under zero stress is not equivalent to the ideal demagnetized state, then this composition may possess positive magnetostriction when compared to the ideal state and hence the measured saturation strain will be less than that predicted from theory. Conversely, if the initial state of magnetization for 27 Tb is closer to the ideal state, the saturation strain will more nearly approach the theoretical value. The 30 Tb composition possesses a higher room temperature anisotropy than 27 Tb and hence the initial states of demagnetization or remanence are likely to be different. When a stress is applied, easy directions perpendicular to the rod are occupied, resulting in a negative magnetostriction compared with the ideal demagnetized state and more available strain on the application of a field.

The observed trend in the initial slope of the plots of magnetostriction versus bias field in Fig. 1 is reflected in the data for the dynamic strain coefficient (d_{33}) as a function of bias field shown in Fig. 2, with 30 Tb performing better under stress bias than 27 Tb. If the dynamic magnetization processes are the same as those under quasistatic conditions, then the burst effect mechanism could be responsible for the differences observed dynamically. The magnitude of the dynamic strain coefficient is not as high as the incrementally determined value (which can be as large as 90 nm A^{-1} for 30 Tb[5]), although we have found that d_{33} increases markedly with the magnitude of the drive field. This field dependence arises because at low drive fields the slope of the minor loop is less than the slope of the static strain curve, but as the drive field is increased, the magnetostriction is forced to execute a loop of greater slope due to the limited width of the hysteresis of the static curve.

Figure 3 shows d_{33} as a function of frequency for the two compositions under stress bias values of 0 and 9 MPa. The observed flat response, which has been reported[6,7] previously for unstressed 27 Tb, is expected because the critical frequency, at which eddy current effects are significant, is greater than 1 kHz. (The similarity between the magnitude of d_{33} under 0 and 9 MPa stress bias is coincidental through the choice of bias field. See d_{33} at 30 kA m^{-1} in Fig. 2.) The graph of Fig. 4 shows the energy loss per cycle (W) as a function of frequency. The observed widening of the static strain hysteresis loop for 30 Tb at 9 MPa is seen to manifest itself in the low frequency energy loss per cycle (W_{hyst}), which has similar values for 27 Tb unstressed and stressed and for 30 Tb unstressed, but which is more than 50% larger for 30 Tb stressed. The data in Table I show that both compositions exhibit higher eddy current loss ($W_{eddy}=W-W_{hyst}$)

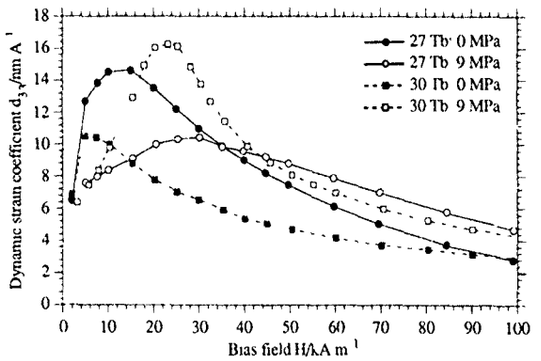

FIG 2 Dynamic strain coefficient as a function of bias field for $Tb_{0.27}Dy_{0.73}Fe_2$ and $Tb_{0.30}Dy_{0.70}Fe_2$ under 0 and 9 MPa stress bias at room temperature using a 70 Hz, 2 kA m^{-1} rms drive field

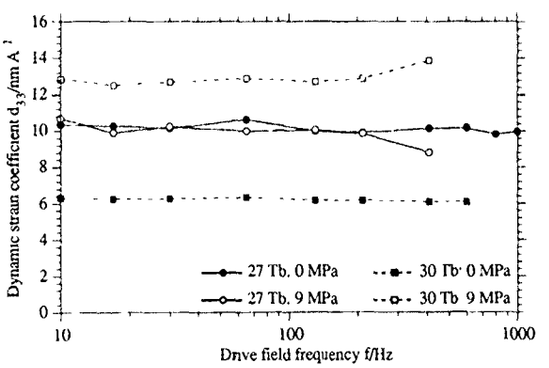

FIG. 3 Dynamic strain coefficient as a function of frequency for $Tb_{0.27}Dy_{0.73}Fe_2$ and $Tb_{0.30}Dy_{0.70}Fe_2$ under 0 and 9 MPa stress bias at a bias field of 30 kA m^{-1} using a 2 kA m^{-1} rms drive field

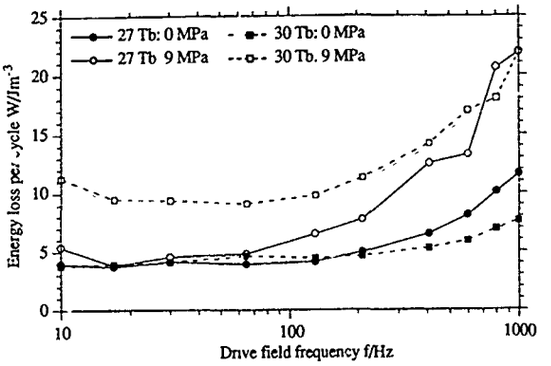

FIG. 4. Energy loss per cycle as a function of frequency for $Tb_{0.27}Dy_{0.73}Fe_2$ and $Tb_{0.30}Dy_{0.70}Fe_2$ under 0 and 9 MPa stress bias at a bias field of 30 kA m^{-1} using a 2 kA m^{-1} rms drive field.

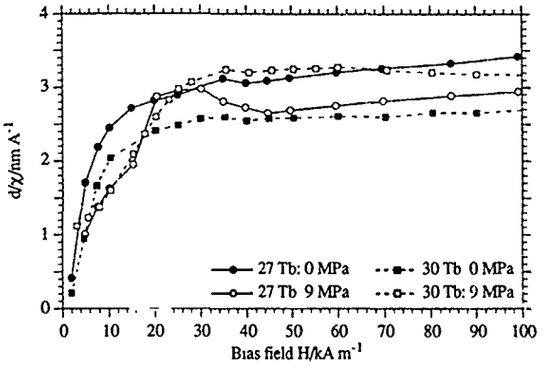

FIG. 5. The ratio d/χ as a function of bias field for $Tb_{0.27}Dy_{0.73}Fe_2$ and $Tb_{0.30}Dy_{0.70}Fe_2$ under 0 and 9 MPa stress bias at room temperature using a 70 Hz, 2 kA m^{-1} rms drive field.

at 1 kHz when stressed, with 27 Tb being the higher. In consequence, the total loss for 27 Tb with stress bias exceeds that for 30 Tb at frequencies above 1 kHz. Part of the increase in apparent eddy current loss can be attributed, from a classical eddy current consideration, to the increase in μ_{r33} at the bias field value used. However, not all of the increase can be accounted for in this way, suggesting that either the eddy current losses behave nonclassically under stress or that other loss mechanisms become significant.

The ratio of the dynamic strain coefficient to the dynamic magnetic susceptibility, d/χ, is a quantity which is dependent only on magnetization processes and material constants and therefore can give information on the magnetization processes taking place.[6,8] This ratio as a function of bias field is shown in Fig. 5 for the two compositions under 0 and 9 MPa stress bias. The two plots for 27 Tb are seen to exhibit similar trends, with the application of stress causing a decrease in the magnitude of d/χ. The plots for 30 Tb also show a similar trend, although in this case the application of stress increases d/χ. These observations suggest that stress bias changes the magnetization processes, but in different ways depending on the composition. Finally we note that at low bias fields, the magnitude of d/χ for 30 Tb is smaller, which suggests an increased number of 180° walls and gives support to the suggestion that different demagnetized states occur for the two compositions.

CONCLUSION

Some of the important magnetomechanical properties are summarized in Table I for the two compositions of Terfenol-D. It is proposed that the performance of transducer devices that are driven at a few kHz would be enhanced by the use of $Tb_{0.30}Dy_{0.70}Fe_2$ when compared to $Tb_{0.27}Dy_{0.73}Fe_2$, not only in terms of the magnetostriction attainable, but also from the point of view of eddy current losses.

Anisotropy in twinned terfenol-D crystals

D. G. Lord and D. Harvey
Joule Physics Laboratory and Science Research Institute, University of Salford, Salford M5 4WT, United Kingdom

The highly magnetostrictive cubic compound Terfenol-D ($Tb_{0.3}Dy_{0.7}Fe_2$) solidifies via a {211} dendritic growth front when grown by a free-standing zone technique. The resulting material is usually composed of dendritic plates often containing crystallographic twins, the predominant plate and twin plane being the $(1\bar{1}1)$ orthogonal to the $(\bar{2}\bar{1}1)$ growth plane. Results of room temperature magnetic torque analysis from (011) disk specimens, having differing twin densities, are presented which yield both the magnetic anisotropy constants, $K_1=-1.6\times10^5$ J/m^3 and $K_2=-0.16\times10^5$ J/m^3, and the relative parent/twin volume. Magnetic susceptibility data both parallel and transverse to the applied field are presented which, in conjunction with the anisotropy results, emphasize the importance of twin density on magnetoelastic response for typical application geometries.

I. INTRODUCTION

The cubic Laves phase ternary compound $Tb_{0.3}Dy_{0.7}Fe_2$ (Terfenol-D) is of significant interest technologically for actuator and transducer applications as it possesses a large magnetostriction to anisotropy ratio near room temperature. Commercially available material, grown by a free-standing zone technique, solidifies via a {211} dendritic growth front producing samples composed of dendritic plates which often contain crystallographic twin boundaries, the predominant plate and twin boundary plane being the {111} orthogonal to the growth front plane.[1,2] Such material exhibits significant magnetoelastic strain, of the order of 1500 ppm in moderate applied fields around 100 kA/m, the development of which, with increasing field, is characterized by discontinuous changes in strain at particular fields.[3]

The magnetic anisotropy, determined by the material composition, is such that anisotropy compensation is achieved at about 280 K;[4] above this temperature, the easy directions for the magnetization are along the ⟨111⟩ axes. It is the anisotropy, influenced by the defect nature of the material, which in the main determines the form of the strain evolution whether this is by domain wall motion or magnetization rotation. The presence of (111) twin boundaries leads to a complication in that not all the easy axes are continuous across either the twin or the dendrite boundaries. In order to gain a better understanding of the interaction of the magnetization and the strain, this article reports room temperature measurements of the anisotropy in such twinned Terfenol-D samples which, along with susceptibility and transverse susceptibility observations, demonstrate the importance of the parent/twin concentration on sample response.

II. EXPERIMENT

Samples used in this investigation were prepared in the form of 8-mm-diam rods by Edge Technologies Inc. by a free-standing zone technique using a zone rate of 38 cm/h. Disk specimens for torque curve analysis, 3 mm in diameter and 1 mm thick, were produced by spark erosion with disk faces parallel to the (011) plane orthogonal to the $(\bar{2}\bar{1}1)$ growth plane. Bar specimens used in measurements of the magnetic susceptibility, 50 mm in length and 5 mm by 5 mm in square cross section, were similarly produced with the long direction parallel to the growth axis and the faces mutually orthogonal and parallel to the (011) and $(1\bar{1}1)$ planes. All planar surfaces, aligned by x-ray back-reflection, were diamond polished to a 1/4 μm finish.

Torque curves were obtained from anti-clockwise rotation of a 650 kA/m magnetic field in the plane of the (100) disks using a Penoyer-type torque magnetometer[5] in which the specimen torque was balanced by an opposing torque produced by a known current passing through a coil, attached to the specimen suspension, which was located in a field from a fixed permanent magnet. All data reported here were taken at a room temperature of 293 K. Differential magnetic susceptibility data were obtained by subjecting the bar specimens to a dc and superimposed ac magnetic field directed along the long bar axis. The ac field of 5 kA/m and frequency 82 Hz was constant, while the dc field was ramped at a rate of 2 kA/m/s. Two pairs of mutually orthogonal pick-up coils were placed around the specimen to detect the transverse magnetization changes in both the $[1\bar{1}1]$ and [011] directions and one coil, with an associated air-flux compensation coil, was placed to detect susceptibility parallel to the applied fields and the $[\bar{2}\bar{1}1]$ direction. Signals in-phase with the ac magnetic field were detected by a lock-in amplifier. All measurements reported were obtained at zero applied stress and at room temperature.

III. RESULTS AND DISCUSSION

The spatial dependence of the magnetocrystalline anisotropy energy, $E(K)$, can be expressed phenomenologically for a cubic crystal as

$$E(K)=K_0+K_1(\alpha_1^2\alpha_2^2+\alpha_2^2\alpha_3^2+\alpha_3^2\alpha_1^2)+K_2(\alpha_1^2\alpha_2^2\alpha_3^2) \quad (1)$$

where K_n are the anisotropy constants and α_i are the direction cosines of the magnetization relative to the cubic axes of the crystal. The presence of both parent(p) and twin(t) oriented material in the specimens is accounted for by assuming a relative fractional parent-to-twin volume, c, such that $c=0.5$ for equal p and t volume content. The magnetic anisotropy energy and magnetization in both parent and twin are of necessity the same: only their relative crystallographic orientations differ. In Fig. 1 we show the anisotropy energy profiles for both twin and parent material superimposed on

 0021-8979/94/76(10)/7151/3/$6.00 © 1994 American Institute of Physics

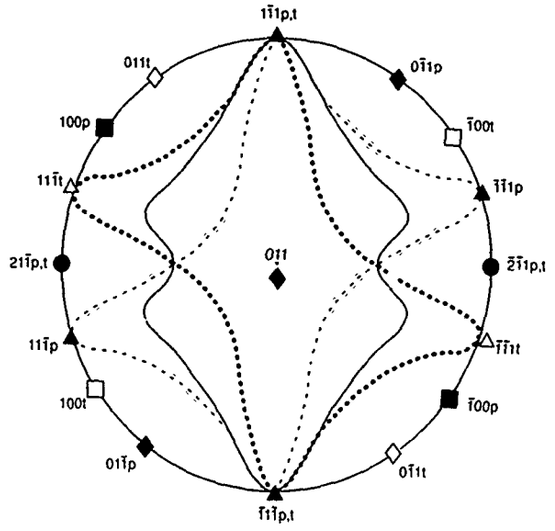

FIG. 1. Polar plot of anisotropy energy superimposed on the stereographic projection of the (011) plane showing parent (p) and twin (t) directions for a (111) twinning plane (dotted and dashed lines represent parent and twin, respectively, and full line represents the energy of the combination of equal parent and twin volumes).

the stereographic projection of the (011) plane of the disk specimen. The profiles are constructed from Eq. (1) using equal negative values of K_1 and K_2 and a K_0 value of half the radius of the projection. The easy ⟨111⟩ directions are clearly indicated by the larger radial values of the profile. Indicated on the figure are the parent and twin directions relative to the predominant (111) twinning plane.[1,2,6] It can be seen from Fig. 1 that the parent and twin are related by a rotation of 70.54° about the surface normal of the (011) plane. The solid energy profile in this figure represents the effective anisotropy energy of the combination of the assumed equal p and t volumes constructed by expressing the energy of the twin in terms of its direction cosines relative to the parent cubic axes. It is this profile that will produce the

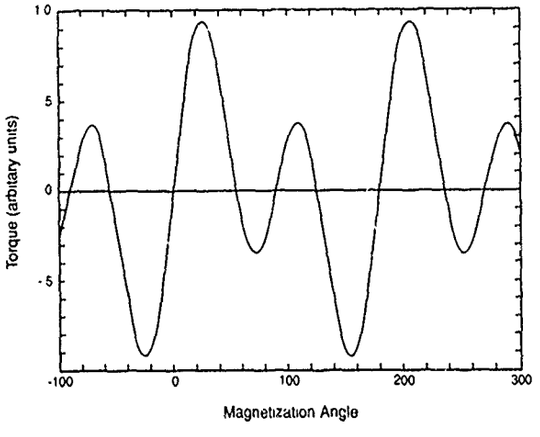

FIG. 2. Expected torque curve from magnetization rotation in the (011) for ⟨111⟩ easy axis cubic crystal. Zero angle is for magnetization along the [100] direction

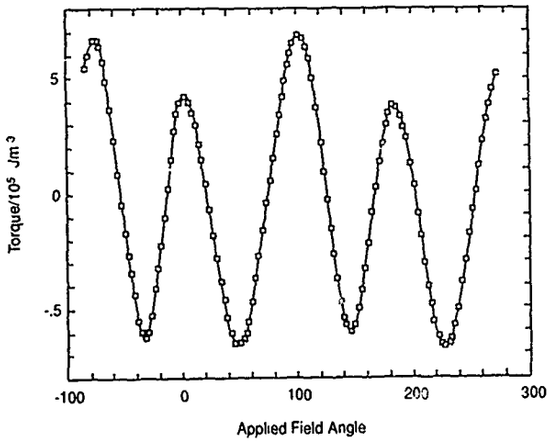

FIG. 3. Experimental torque curve from Terfenol-D (011) disk Zero angle is for field (650 kA/m) along parent [100] direction

resulting torque curve where the torque, corrected for misalignment of the field and the magnetization, is $-dE(K)/d\theta$, θ being the field angle with respect to the parent [100] direction.

The torque expected from an untwinned disk is shown in Fig. 2 and can be compared to an experimental curve from a (011) twinned sample shown in Fig. 3. Torque curves have been obtained from a number of samples, of differing twin density, and analyzed by a curve fitting procedure to yield both the relative twin density c and the anisotropy constants. The values found are $K_1 = -(1.60 +/- 0.08) \times 10^5$ J m^{-3} and $K_2 = -(0.16 +/- 0.01) \times 10^5$ J m^{-3} which compare favorably with previous data for K_1 though not with the previous scattered data for K_2. The values of c have been correlated with estimates of twin density from polarized optical micrographs of the disk surfaces, two examples of which are

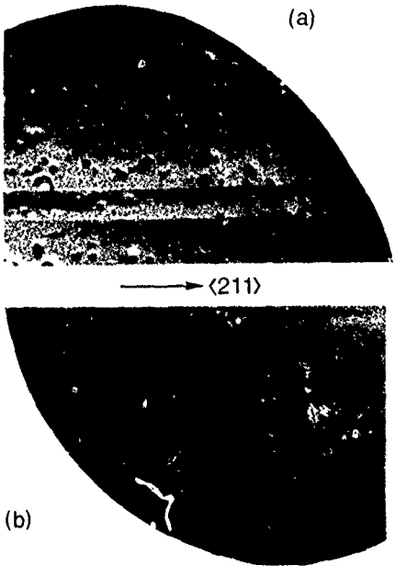

FIG. 4 Polarized optical micrographs from (011) Terfenol-D disks showing differences in twin (darker areas) density between disk (a) and disk (b).

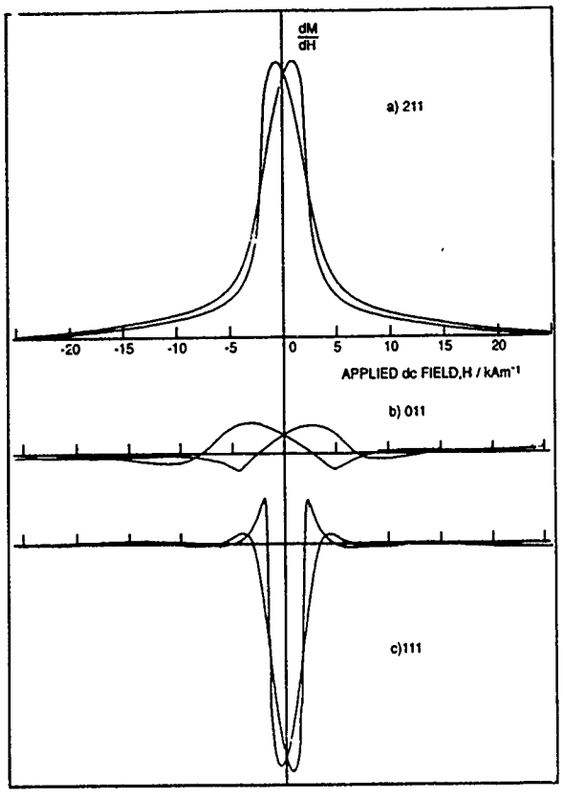

FIG. 5. Differential magnetic susceptibility data measured parallel to (a) [211] growth direction, (b) [011], and (c) [111] where applied dc and ac fields are parallel to [211]. Sensitivity for (b) and (c) is approximately ten times greater than for (a).

shown in Fig. 4, where the twins correspond to the lower reflectance areas and the straightness of the twin boundaries are clearly observed. Excellent agreement has been found for values of c between 0.3 as in Fig. 4(a) and 0.5 (the more typical material) as in Fig. 4(b).

Differential susceptibility and transverse susceptibility data in the mutually orthogonal $[\bar{2}\bar{1}1]$, [011], and $[1\bar{1}1]$ direction from a bar specimen with an optically estimated parent/twin density of $c=0.45$ is shown in Fig. 5. For a specimen with $c=0.50$, it may be expected that the high symmetry of the anisotropy energy about the $[\bar{2}\bar{1}1]$ bar axis, as seen in Fig. 1, would yield zero transverse magnetization as there would be equal populations distributed symmetrically with respect to the bar axis, even accounting for the anisotropic effect of the magnetostriction.[7] The small transverse susceptibility signals from the [011] and $[1\bar{1}1]$ are therefore due to the asymmetry in the anisotropy energy introduced by the inequality in parent and twin volumes. Indeed, the variations show excellent agreement both in field dependence and magnitude to the magnetostriction data obtained in these directions[3] and indicate that the magnetization distribution, as a function of applied field, is far from straightforward.

IV. CONCLUSIONS

The magnetic anisotropy constants in twinned Terfenol-D materials have been obtained from room temperature torque curve analysis from (011) plane disk specimens of varying twin content. Consideration of the anisotropy energy as a function of twin content clearly demonstrates the potential symmetry of currently available float-zone material for the case of equal parent/twin volumes. Where any inequality exists, the anisotropy, and hence magnetoelastic strain, will be asymmetrically disposed to the growth direction. The only crystal direction in which behavior is symmetrical in twinned or untwinned material is the ⟨111⟩ normal to the predominant twin plane. To manufacture device material using such a geometry would yield large strains with exceptional strain coefficients as seen from the ⟨111⟩ data in Fig. 5.

Device oriented magnetoelastic properties of $Tb_xDy_{1-x}Fe_{1.95}$ ($x=0.27$, 0.3) at elevated temperatures

K. Prajapati, R. D. Greenough, and A. G. Jenner
Department of Applied Physics, University of Hull, Hull HU6 7RX, United Kingdom

In order to assess the potential of the highly magnetostrictive compound Terfenol-D (composition $Tb_xDy_{1-x}Fe_{1.95}$, where $x=0.3$ or 0.27) for device applications in the temperature range 20–300 °C, measurement of magnetostrictive strain (λ), differential strain coefficient (d_{33}), and magnetomechanical coupling coefficient (k_{33}) have been made against applied dc field ($\leq$120 kA/m), uniaxial pressure ($\leq$20 MPa), and temperature. Comparing the two compositions at elevated temperatures has shown that large grain oriented material of the composition $Tb_{0.3}Dy_{0.7}Fe_{1.95}$ has higher strains and d coefficients at elevated temperatures than small grain oriented material of composition $Tb_{0.27}Dy_{0.73}Fe_{1.95}$, but for optimum coupling efficiency $Tb_{0.27}Dy_{0.73}Fe_{1.95}$ is preferable.

I. INTRODUCTION

The pseudobinary rare earth-iron compound Terfenol-D[1] ($Tb_xDy_{1-x}Fe_{1.95}$, where x is typically 0.27 or 0.3) generates large magnetostrictive strains (~1500 ppm) which can be used in a variety of applications. For a particular composition, the magnetomechanical properties depend on three principal factors: the applied field, temperature, and especially in grain oriented material, the applied stress.[2] Although some measurements have been made at elevated temperatures,[3] previous work has concentrated mainly on the room temperature properties. However, operation at higher temperatures is desirable for some applications and the present work was conducted to provide a more comprehensive assessment of magnetomechanical performance to temperatures up to 300 °C.

The two main constraints on the range of temperature over which Terfenol-D can be used are (i) the magnetocrystalline anisotropy, because at low temperatures the competing anisotropies of the Tb and Dy ions causes the easy axis of magnetization to switch from the $\langle 111\rangle$ to the $\langle 100\rangle$ axes,[4] and (ii) the exchange energy which decreases as the temperature approaches the Curie temperature, T_c, and causes the magnetostriction to decrease monotonically in accordance to single ion theory.[5] Within these constraints lies a useful range of temperature and the following results indicate how the performance of Terfenol-D can be optimized in this range.

The two compositions chosen for comparative purposes are $x=0.30$ (grain oriented, large grains), which is particularly susceptible to the application of applied uniaxial prestress along the $[11\bar{2}]$ grain growth axis,[6] and $x=0.27$ (grain oriented, small grains), chosen to minimize magnetocrystalline anisotropy at room temperature.[1] The grain structure in both compositions is typical of commercially available material.

II. EXPERIMENTAL TECHNIQUES

Commercial grade samples, prepared by a free float zone process, were in the form of rods 50 to 100 mm long and 6 mm diameter, with the $[11\bar{2}]$ growth direction along the rod axis. Magnetostrictive strain, λ, measured with strain gauges, were measured in dc fields $\leq$120 kA/m and with uniaxial stresses $\leq$20 MPa applied along the $[11\bar{2}]$ axis. The magnetostrictive strain coefficient $d_{33}(=d\lambda/dH)$ were obtained by differentiating the static λ-H curves. Coupling coefficients (k_{33}) were obtained from the magnetomechanical resonance. The measurements were undertaken in a noninductively wound furnace to obtain temperatures $\leq$300 °C (±1 °C) with samples contained in an argon atmosphere. Approximately 5% variation in measurements from sample to sample was expected and found.

III. RESULTS AND DISCUSSION

Data have been collected for λ, d_{33}, and k_{33} as functions of applied field, stress, and temperature. For each magnetostriction isothermal in Figs. 1 and 2, the uniaxial pressure and applied field have been chosen to yield the maximum d coefficient. At room temperature for $x=0.3$, after a sharp increase in strain at low fields (known as the "burst effect"[4]), at 120 kA/m the strain is almost doubled. The isofield contours decrease slowly with temperature at low

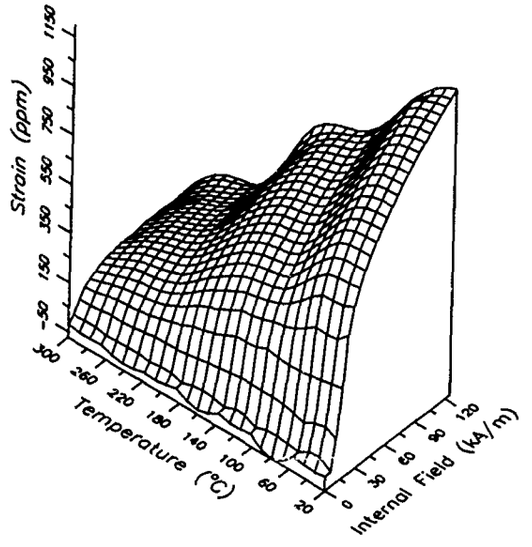

FIG. 1. Strain profile at optimum pressure bias conditions for maximum d_{33} as a function of temperature and internal magnetic field for $x=0.30$ composition.

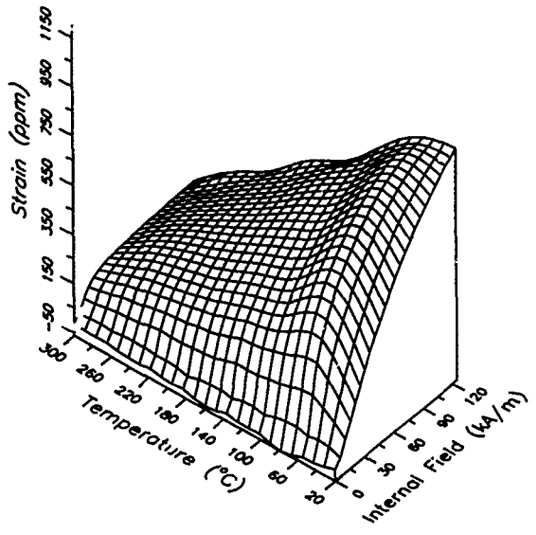

FIG. 2. Strain profile at optimum pressure bias conditions for maximum d_{33} as a function of temperature and internal magnetic field for $x=0.27$ composition.

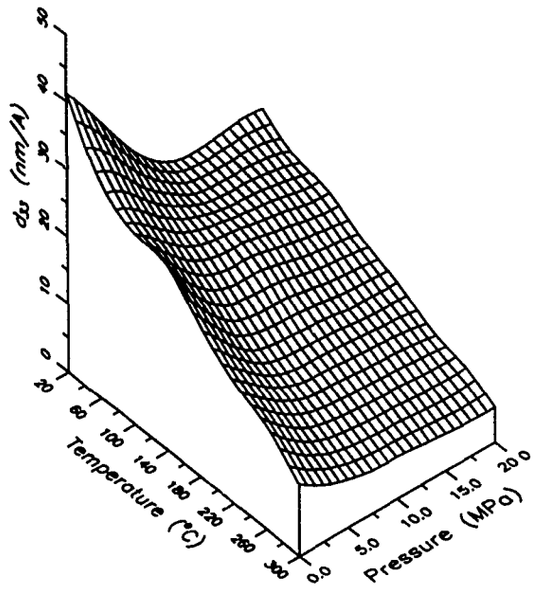

FIG. 4. Variation in optimum d_{33} with pressure and temperature for $x=0.27$.

fields (<30 kA/m) but the decrease in the 120 kA/m contour in this sample is clearly not monotonic. Although magnetic saturation has not been achieved, it is expected that these strains should decrease with temperature approximately as m^3 [where m is the reduced magnetization (M_T/M_0)].[5] The maximum at ~140 °C interrupts this pattern and is evident in fields as low as 30 kA/m. For practical applications this effect at 140 °C is an added bonus because unexpectedly larger strains can be generated. For the sample with $x=0.27$ the decrease in isofield strains with temperature are almost monotonic for any field strength. The different behaviors of the $x=0.3$ and 0.27 samples is explained by the competing anisotropies of the Tb and Dy ions. For $x=0.3$ the anisotropy minimum is at $T=-10$ °C with maximum strains at 25 °C; and for $x=0.27$, the minimum in anisotropy occurs at approximately $T=20$ °C, with the maximum strain at ~60 °C (comparable with findings by Clark *et al.*[3]).

Along each isothermal contour for d_{33} (Figs. 3 and 4) fields have been applied to give the largest d coefficient for each applied pressure. For $x=0.3$ in the range $20 \leq T \leq 200$ °C, an enhanced d coefficient is present at low pressures due to the combined effects of applied stress and grain orientation.[4] The level of stress becomes less critical for $T>200$ °C, where the small magnetocrystalline anisotropy[5] renders the applied stress less effective in regu-

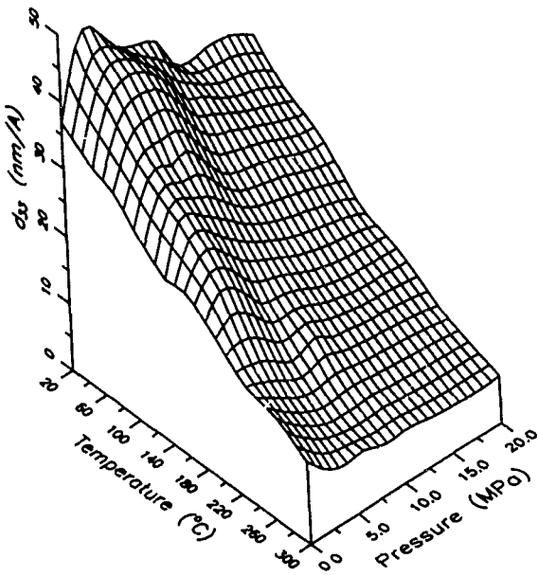

FIG. 3. Variation in optimum d_{33} with pressure and temperature for $x=0.30$

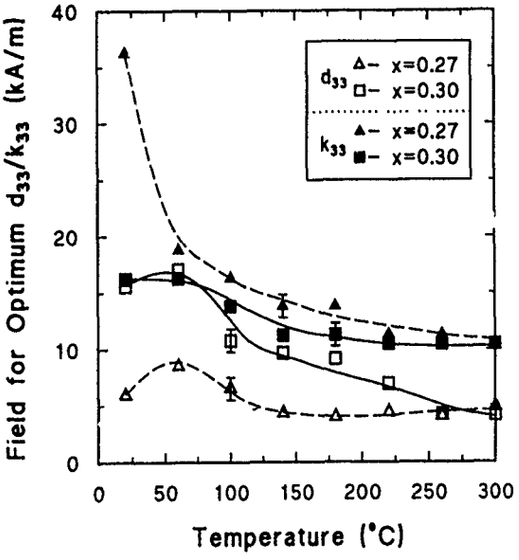

FIG. 5. dc bias fields required to obtain maximum d_{33} and k_{33} as a function of temperature for $x=0.27$ and 0.30.

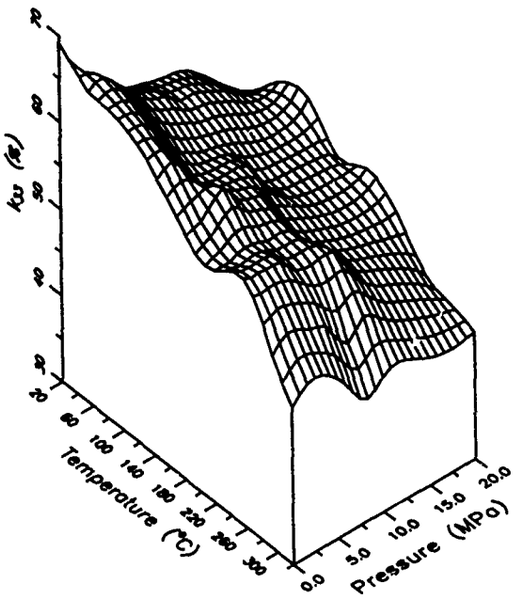

FIG. 7. Surface plot showing the variation in optimum k_{33} with pressure and temperature for $x=0.27$.

lating the magnetization processes. This is the case for $x=0.27$ at most temperatures until an imbalance between the Tb and Dy anisotropies emerges at low temperatures ($T\leqslant 40$ °C). Due to the magnetocrystalline anisotropy, undulations occur in the d_{33} surface for $x=0.30$, whereas this surface for $x=0.27$ is comparatively smooth. The oscillation on the room temperature isothermal for $x=0.30$ have been observed in other samples with the same composition and are reported elsewhere.[7] From the application point of view there is a clear advantage in employing Terfenol-D with $x=0.30$ for $T\leqslant 100$ °C. Provided pressure loading is kept in the range 2–10 MPa. Larger fields are required compared with $x=0.27$ (Fig. 5) and some control will be needed to maintain them in the range 10–17 kA/m.

The surfaces representing optimum magnetomechanical coupling as a function of temperature and pressure are very irregular for both compositions (Figs. 6 and 7). This is not surprising because k_{33} depends on d coefficient, permeability, and elastic compliance.[2] At elevated temperatures ($T\sim 300$ °C), for $x=0.30$, k_{33} is very strongly dependent on pressure. It decreases from ~0.5 to ~0.35 between zero and 7 MPa, representing a reduction in transducer efficiency from 25% to 12%. For $x=0.27$ the lowest observed value for k_{33}, regardless of pressure or temperature is ~0.45. It is concluded that pressure dependent effects on k_{33} in large grain oriented material are a disadvantage and small grain oriented material ($x=0.27$) is preferable.

IV. CONCLUSIONS

For practical applications the present results show that large grain oriented material with the composition $Tb_{0.3}Dy_{0.7}Fe_{1.95}$ produces better strain and d coefficients at elevated temperatures provided the applied field is controlled. For optimum coupling efficiency at elevated temperatures, the small grain oriented material with composition $Tb_{0.27}Dy_{0.73}Fe_{1.95}$ is preferable.

Influence of hydrogen on the magnetic properties of Terfenol-D

L. Ruiz de Angulo, J. S. Abell, and I. R. Harris
School of Metallurgy and Materials, University of Birmingham, Birmingham, United Kingdom

The reactions with hydrogen of the C15-type Laves phase $Tb_{0.27}Dy_{0.7}Fe_2$ have been studied by differential thermal analysis and the influence of this hydrogenation upon the magnetic properties was observed with a Curie–Faraday balance and a vibrating sample magnetometer. It has been found that a slightly rare earth rich composition allows the hydrogenation to take place at room temperature. Two endothermic peaks observed on heating under 1.2 bar of hydrogen are attributed to hydrogen desorption, due possibly to the form of the pressure isotherms. At a pressure of 1.2 bar, the amorphization and disproportionation peaks are combined as a single peak, but a higher pressures these two phenomena separate into two peaks. After the first absorption/desorption cycle, the hydrogenation occurs at temperatures as low as −75 °C, and is highly exothermic and very rapid in nature. The magnetic susceptibility of the compound suffers a dramatic drop when it is hydrided, and the magnetization at 1100 kA m^{-1} falls from 77.5 J T^{-1} kg^{-1} to 9.2 J T^{-1} kg^{-1}. When heated in hydrogen, a peak in susceptibility was observed at about the same temperatures as those of the amorphization/disproportionation reactions. The Curie point of the amorphous hydrided material was found to be around 68 °C, with a magnetization at room temperature and 1100 kA m^{-1} of 46 J T^{-1} kg^{-1}. The fully disproportionated material had a magnetization of 82 J T^{-} kg^{-1} at 1100 kA m^{-1}, which was related to the proportion of α-Fe formed during the disproportionation reaction.

I. INTRODUCTION

The RTM_2 (R=rare earth, TM=transition metal) type Laves phase compounds have been studied in the last few years for their interesting magnetic properties and hydrogen-absorption capacity, see, for example, Refs. 1–2. Upon hydrogenation, these compounds exhibit substantial changes in their magnetic properties. In addition, the pseudobinary Terfenol-D ($Tb_{0.27}Dy_{0.73}Fe_2$) has outstanding magnetorestrictive properties combining a low crystalline anisotropy with a huge magnetorestriction at room temperature.[3] In the light of these studies, it is therefore interesting to investigate the hydrogenation behavior of this compound.

II. EXPERIMENT

The material used in the present work was $Tb_{0.27}Dy_{0.73}Fe_{1.93}$ ($RFe_{1.93}$). Lumps (a single coarse particle of ≈200 mg) were introduced to a specially constructed differential thermal analyzer (DTA) with a hydrogen atmosphere (HDTA), and were subjected to different pressures with a heating rate of 3 °C per min. The material obtained was used for measurements on a vibrating sampler magnetometer (VSM), and for x-ray diffractometry using Co K_α and Cu K_α radiation. Curie–Faraday balance measurements were performed by hydrogenating freshly cut lumps of around 30 mg, *in situ*. In this case, a hydrogen pressure of 1 bar was employed.

A. Hydrogen absorption

HDTA was performed in order to investigate the influence of the rare earth grain boundary phase on the hydrogenation process. It was found that, when the material was single phase and in lump form, the hydrogenation process took place at about 280 °C, and at about 120 °C when in the form of crushed powder. However, the compound $RFe_{1.93}$ (3.5 at. % of free rare earth) reacts very rapidly at temperatures close to room temperature, even as a lump. Figure 1 shows the HDTA trace of lumps of $RFe_{1.93}$ heated in a hydrogen atmosphere at 1.2, 3, and 5 bar initial pressure.

Three exothermic peaks and two endothermic peaks were seen in the trace, corresponding to the run at 1.2 bar of H_2. At higher pressures four, exothermic peaks, but only one endothermic peak, were observed. X-ray diffraction examination of the material was carried out after each peak of the 1.2 bar run. After the first exothermic peak, the material had an expanded cubic structure, indicating hydrogen absorption in the crystalline state. The x-ray diffraction (XRD) patterns of the samples hydrogenated after each endothermic peak showed different rhombohedral structures. On hydrogenation at 400 °C, very broad x-ray peaks corresponding to RH_2 and α-Fe could be seen. At temperatures above 500 °C, much sharper peaks, corresponding to RH_2 and α-Fe were observed. When heated under 5 bar to 300 °C, no x-ray peaks, but a broad maximum, can be observed, thus indicating

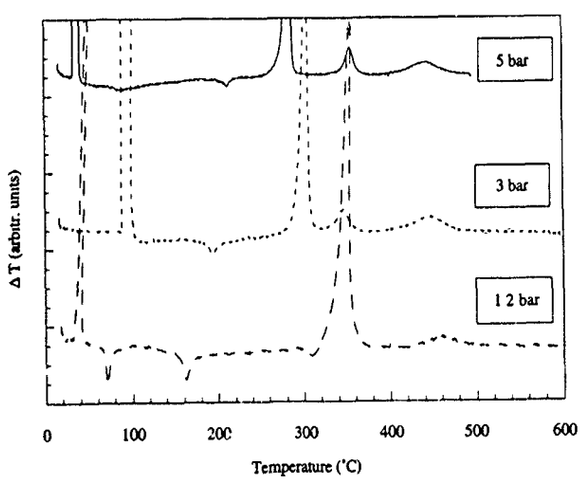

FIG. 1. HDTA traces of $Tb_{0.27}Dy_{0.73}Fe_{1.93}$($RFe_{1.93}$) at different pressures.

 0021-8979/94/76(10)/7157/3/$6.00 © 1994 American Institute of Physics

amorphous material. Finally, the diffraction pattern of the sample heated under 5 bar to 400 °C is very similar to the one heated to the same temperature at 1.2 bar. The endothermic peaks move to higher temperatures with increasing pressure, and this could indicate that they are related to the form of the pressure isotherms rather than to any change in the structure or state. This data are consistent with the work of others researchers.[2,4]

These results indicate that, below 280 °C in this range of pressures, Terfenol-D absorbs hydrogen while maintaining a crystalline structure. The second exothermic peak observed at 1.2 bar can be ascribed to the combination of the hydrogen induced amorphization and the disproportionation reaction. These two reactions separate at higher pressures due to a lowering of the amorphization temperature. This lowering of the amorphization temperature with pressure has already been reported in other Laves phases such as $TbFe_2$ (Ref. 5) and $GdFe_2$ [6]

It was observed that, when cycles of absorption/desorption were performed, the initial hydrogenation reaction would take place immediately at room temperature. To investigate if this could be done at lower temperatures, a lump of $RFe_{1.93}$ was hydrided, and then desorbed by heating under vacuum to 350 °C and then cooled. At room temperature, 5 bar of argon was introduced, and the sample chamber was cooled with liquid nitrogen. When the temperature was −125 °C, the argon was replaced by 1.2 bar of H_2. At around −75 °C, a sharp and strong exothermic peak (ΔT=52 °C) was observed. From this point and apart from the hydrogen absorption peak at 40 °C, the trace was the same as that for 1.2 bar H_2 shown in Fig. 1. One possible contribution to the low hydrogenation temperature is the very clean surface obtained in this material after hydrogen decrepitation. This behavior also indicates very rapid hydrogen diffusion in this system.

B. VSM measurements

Figure 2 shows the magnetization obtained for $RFe_{1.93}$ material heated in hydrogen at 1.2 bar to different temperatures. It can be seen that the cubic hydride is still unsaturated at 1100 kA/m, giving a magnetization of 9.2 J T^{-1} kg^{-1}. The rhombohedral hydrides (70 °C and 160 °C) exhibit a behavior close to paramagnetism. These observations agree with work by Annapoorni *et al.*[2]

The sample heated to 400 °C is easier to magnetize, and a magnetization at 1100 kA/m of 50 J T^{-1} kg^{-1} was obtained. From the experiments on the HDTA, this value should correspond to a mixture of amorphous plus very finely disproportionated material. To measure the real value of the amorphous material, one sample was heated under 5 bar of hydrogen up to 300 °C and then quenched. The XRD studies confirmed the amorphous state of the material. The amorphous material was found to be easy to magnetize, and a magnetization at 1100 kA/m of 46 J T^{-1} kg^{-1} was obtained. The sample heated to 500 °C at 1.2 bar had a magnetization of 82 J T^{-1} kg^{-1} at 1100 kA/m. This value is close to the theoretical value of 86 J T^{-1} kg^{-1} expected for a fully disproportionated material consisting of α-Fe and RH_2.

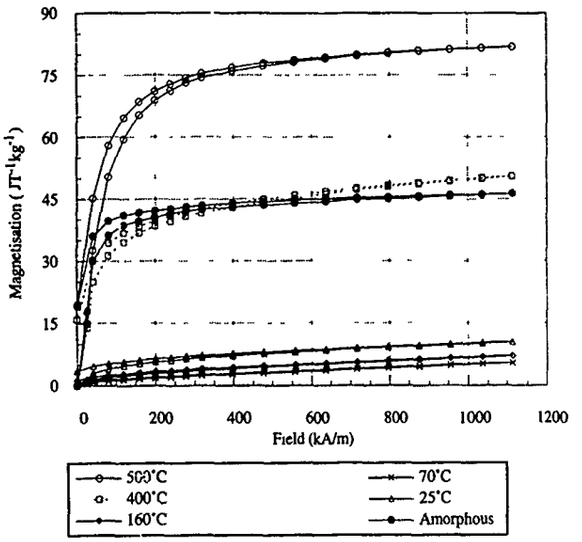

FIG. 2. Magnetization of $RFe_{1.93}$ samples heated in 1.2 bar H_2 to different temperatures and in 5 bar H_2 to 300 °C (amorphous).

C. Curie–Faraday balance experiments

The results of the Curie–Faraday balance experiment are shown in Fig. 3. Upon hydrogenation, there is a sudden drop in magnetic susceptibility, which is consistent with the VSM measurements. Between 350 and 520 °C, the susceptibility increases as the hydrogenated material starts to disproportionate, with the formation of α-Fe. On cooling, the susceptibility increases steadily, as would be expected from the presence of free iron.

After the initial drop at 57 °C, the susceptibility decreases slowly with the temperature up to around 180 °C, after which the temperature exhibits an increase. Another interesting feature is the peak between 260 and 350 °C, which is approximately the temperature range where the HDTA displays the combined amorphization/disproportionation peak. The increase in magnetic suscepti-

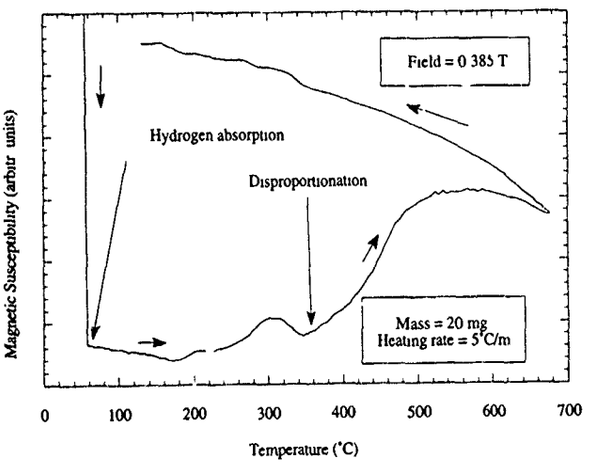

FIG. 3. Curie–Faraday balance trace of $RFe_{1.93}$ heated under 1 bar of hydrogen.

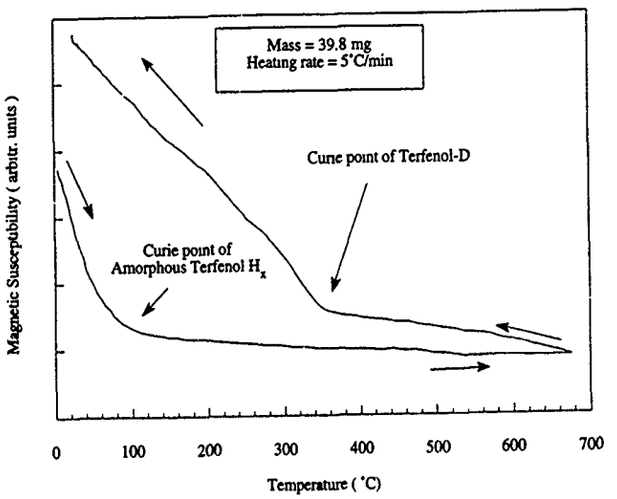

FIG. 4. Curie–Faraday balance trace of hydrogen induced amorphized $RFe_{1.93}$ heated under vacuum.

bility from 180 to 300 °C could be related to the loss of hydrogen prior to amorphization, as suggested by Manwaring *et al.*[7] What is not understood at this stage is the reason for the decrease in susceptibility from 300 to 350 °C.

Finally, 39.8 mg of $RFe_{1.93}$ were hydrogenated in the Curie–Faraday balance, heated to 380 °C, and then cooled. After this treatment, the resulting material should be mainly amorphous. After evacuating the chamber, the sample was heated under vacuum. The resultant trace is shown in Fig. 4. On heating, it can be seen that the Curie point for the amorphous Terfenol-D hydride, under these conditions, is around 68 °C (in this work the Curie point was defined as the intersection of the tangents of the two different parts of the curve). On cooling, another Curie point can be observed at around 370 °C. These results show that, when heated under vacuum, the hydrogen amorphized Terfenol reverts to its original crystalline structure.

D. Conclusions

The pseudobinary Laves phase, Terfenol-D, exhibits interesting and complex reactions with hydrogen. The initial hydrogenation can take place at a very low temperature under low hydrogen pressure. As is the case with other RTM_2 compounds, it is possible to induce amorphization with the introduction of hydrogen in the structure. The transformation of the rhombohedral hydride structure to the amorphous state is accompanied by a recovery of magnetization at room temperature. This amorphous material has a Curie point close to 70 °C.

A. J. Wilkinson
Department of Electronic Engineering, University of Hull, Hull HU6 7RX, United Kingdom

A vibration control case study is described which demonstrates the application of magnetostrictive (Terfenol-D) actuators. The magnetomechanical properties of the material suggests that when incorporated in devices for applications a nonlinear response will result. This case study compares the performance of two kinds of control strategy (both discrete), a conventional proportional and integral (PI) algorithm and a variable structure algorithm (DVSC) in both servo and cancellation/regulation roles. Both strategies were implemented on an INMOS[7] transputer based microcontroller with a sampling period of 300 μs. The results presented show that the control behavior of the DVSC strategy offers significant advantages over the PI strategy when controlling actuators with nonlinear characteristics, i.e., the rejection of a 5 Hz disturbance with a gain of -36 dB compared to a gain of -15 dB when using the PI strategy.

I. INTRODUCTION

The exceptional magnetomechanical properties of the rare earth compounds generically known as Terfenol-D, have been shown to offer a great potential for a variety of transducer and actuator applications.[1,2] This potential is now being realized with the development of linear and rotary actuators but such devices usually require advanced instrumentation to implement servo controlled loops, for example, linear micropositioning or active vibration control.[3]

Actuator/transducer performance is sensitive to operating conditions and requires device designs to take into account the specification and working conditions that are unique to each application. This sensitivity is due to the nonlinear response of Terfenol-D.[4] To achieve control over operating performance, strategies are employed that cater to both the nonlinear magnetomechanical material properties and the responses from the associated mechanical components. At best, the overall system response can be considered linear with a gain that varies with the operating point.[3]

Here, servo actuators that achieve predescribed displacement wave forms (i.e., triangle, sine or step) are described. These form the basis of an active vibration control (AVC) system in which two types of control algorithms (both discrete) are incorporated, a conventional proportional and integral (PI) type and a variable structure control (DVSC) type. A vibration control case study is presented to compare these two types of control algorithms.

II. EXPERIMENTAL TECHNIQUES

In order to demonstrate the potential of Terfenol-D in servo actuators and in active vibration control (AVC), Terfenol-D based actuators were constructed and two of these incorporated in a system arranged in the form of one table carried by another (Fig. 1). These actuators have built-in adjustable prestress to place the material on the optimum gain magnetostriction curve, permanent magnets to bias the material in the middle of the approximately linear region of the strain (λ)-field (H) curve, a drive coil to implement actuation signal, and a complete magnetic circuit to reduce flux loss.[3]

The actuators in the system can be used as individual units to implement servo tests or together with the lower actuator causing a disturbance of the level two table for antivibration (AV) tests. The aim of the AV control is to minimize the impact of any disturbance on the level one table using only the measurement of the position via linear variable displacement transducers (LVDTs), type GTX2500 (RDP, Ltd., Wolverhampton, UK) of the two tables to create a drive signal for the top actuator. Two control algorithm types, a conventional proportional and integral (PI) type, and a variable structure control (DVSC) type, both discrete, were implemented on a INMOS[5] transputer based microcontroller with a sampling period of 300 μs.[4]

III. RESULTS AND DISCUSSION

The overall response of the level one table/antivibration actuator system must be linear and of appropriate speed and character in order to cancel the vibration of the level two table. This must be achieved in spite of the nonlinear behavior of the Terfenol-D material. The presence of sensor two

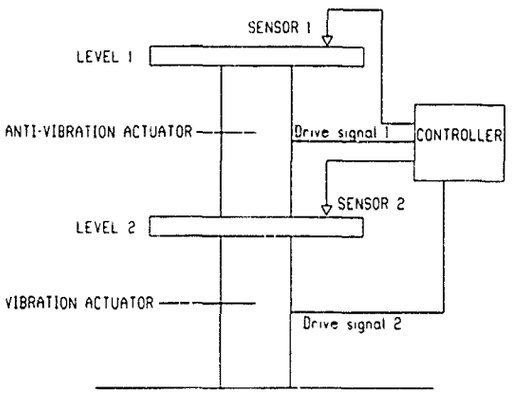

FIG. 1. Schematic of vibration experiment consisting of a vibration table in the form of one table carried by another.

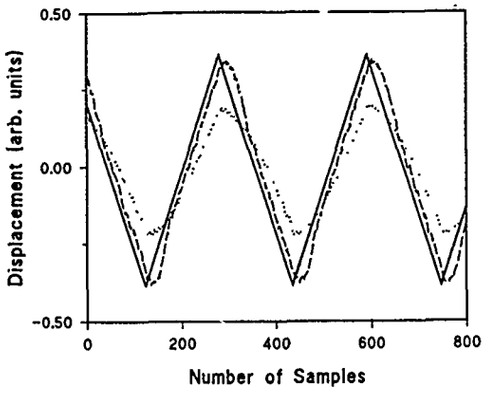

FIG. 2. Displacement of level one table position under DVSC (---) and PI (···) control in response to a triangular demand signal (—).

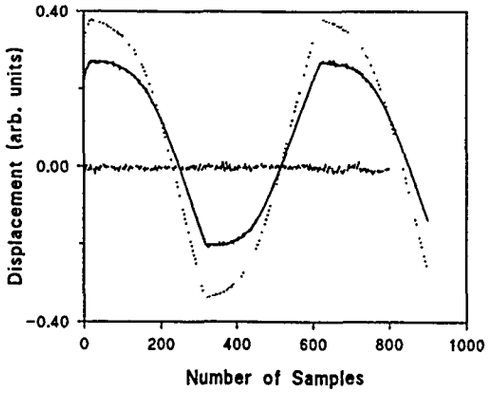

FIG. 4. Table displacements in response to a 5 Hz vibration actuation drive signal. Level one table displacement (—), level two (···), and "canceled" level one displacement under DVSC control as reference (~-~-~).

offers the possibility of using feed-forward control strategies to reduce the effects of the disturbance on the level one table.

To test the actuators and the control algorithms servo experiments were implemented with the use of predetermined demand displacement wave forms. The response of level one actuator to both triangular and step demand (frequency 10 Hz) signals supplied to the DVSC and PI controllers is shown in Figs. 2 and 3. No drive is supplied to the vibration actuator (level 2) in these experiments. It can be seen that the DVSC algorithm shows a superior signal following property particularly when using a step demand, it has the ability to suppress the excitation of unwanted mechanical resonances whilst responding to the demand in a desired way.

Variable structure control (VSC) is a modern nonlinear switching control technique[6] which can be described, for a second order process, as a means of constraining the dynamic behavior to that of a desired first order process response using switched feedback control, i.e., switching between positive and negative feedback. In the implementation of this control approach, the feedback gains which are switched are typically much larger than those used in PI control. Thus, there is an equivalent increase in control system immunity to process gain and behavior variations such as those caused by Terfenol-D. Here, the approach used to control the level one actuator was to use a computer based form of VSC with a discrete form of the switching line.[7] In a practical device such as the level one actuator, additional compensation dynamics must be used to ensure good performance, such as the incorporation of integral action to prevent steady state errors which may cause the DVSC to act inappropriately. If in certain situations the dynamics of the device are suspected to be higher than second order, then lead compensation in the form of discrete zeros must be incorporated into the feedback signal path. This prevents higher order resonances from being excited by the DVSC control.

The response of the level one and level two table to a 5 Hz drive signal applied to the vibration actuator when the DVSC controller is used to drive the antivibration actuator is shown in Fig. 4. The difference between using either PI or DVSC control to drive the antivibration actuator in cancellation is highlighted in Fig. 5, using the same input drive levels shown in Fig. 4, with the resulting amplitude reduction for each type (from spectrum analysis at 5 Hz) as −15 and −36 dB for the PI and DVSC algorithms, respectively.

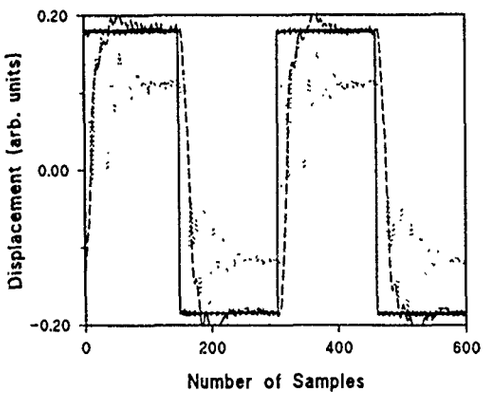

FIG. 3 Displacement of level one table position under DVSC (---) and PI (···) control in response to a step demand signal (—).

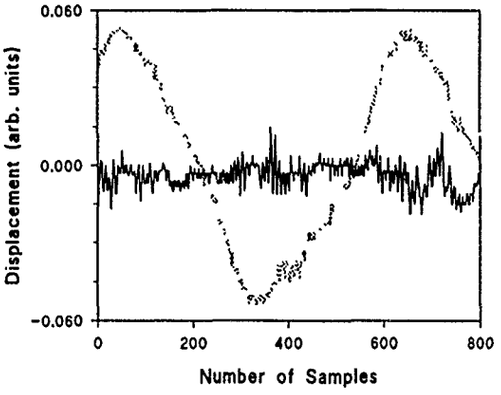

FIG. 5. Relative "canceled" level one table displacements under DVSC (—) and PI (·) control showing reduced effects of a 5 Hz vibration actuator drive signal using the same drive levels as shown in Fig. 4.

IV. CONCLUSION

Antivibration control has been illustrated with Terfenol-D based actuators incorporated in a device consisting of one table carried by another. Two implementations of computer based control have been demonstrated, a PI algorithm and a novel DVSC approach. Both algorithms were implemented using an INMOS[7] transputer based microcontroller. The DVSC algorithm demonstrated superior antivibration and demand signal following properties, with a resulting −36 dB in amplitude cancellation for a 5 Hz vibration signal. The DVSC approach showed particular superior behavior in its response to a step demand. It appeared to be able to suppress the excitation of unwanted mechanical resonances while at the same time responding to the step demand in a desired way.

Pressure dependencies of magnetostrictive strain and *d* coefficient in Terfenol-D after thermal or magnetic annealing

N. Galloway,[a] R. D. Greenough, A. G. I. Jenner, and M. P. Schulze
Department of Applied Physics, University of Hull, Hull HU6 7RX, United Kingdom

The pressure dependence of the magnetostrictive strain coefficient, d_{33}, and maximum strains in applied fields of 120 kA m^{-1} have been measured in samples of Terfenol-D before and after thermal or magnetic annealing. Application of an annealing field, H_a, parallel to the ⟨111⟩ axes which are normal to grains oriented along the [11$\bar{2}$] axis, leads to an increase in d_{33} of as much as 81%, with applied uniaxial prestresses as low as 3 MPa. The variation of optimum d_{33} values as a function of stress applied along the [11$\bar{2}$] axis shows anomalous oscillations after magnetic annealing. The thermal and magnetic effects of the annealing procedures are discussed and a mechanism to explain magnetic annealing is proposed.

INTRODUCTION

Investigations have been made previously into the effects of thermal[1] and magnetic[2,3] annealing on the magnetostrictive properties of Terfenol-D. Of these, the most comprehensive study was made by Verhoeven on grain oriented samples with the annealing fields applied parallel to the ⟨111⟩ axes which are perpendicular to the [11$\bar{2}$] grain growth direction. After heat treatment followed by magnetic annealing, one particular sample ($Tb_{0.318}Dy_{0.682}Fe_{1.963}$) subsequently produced an increase in the maximum anisotropic magnetostrictive strain, λ_{max}, measured in an applied field of 3 kOe and, more striking, an unusually large magnetostrictive strain coefficient, d_{33} $(=d\lambda/dH)$ in the absence of any applied uniaxial stress. The application of a prestress is usually considered essential to generate such a response in samples which have not been subjected to magnetic anneal.[4] As part of the same investigation, other samples still required ~1.7 MPa to obtain enhanced levels of λ_{max} and d_{33}, even after magnetic annealing.

The response to a magnetic field anneal depends on the conditions of the samples prior to the anneal. Grain orientation is clearly essential and while the rare earth (RE)-iron ratio regulates the magnetoelastic coupling, the Tb:Dy ratio controls the magnetocrystalline anisotropy. The consequences of these two compositional factors are not unrelated; the application of a uniaxial prestress induces additional anisotropy via the magnetoelastic coupling which, by virtue of the sign of the magnetostriction, causes magnetic moments to rotate away from the stress axis. The purpose of the present work is to investigate the effects of thermal annealing which can induce compositional changes and magnetic annealing which induces magnetic anisotropy. Of particular interest are the resultant magnetostrictive properties gauged by the pressure dependencies of λ_{max} and d_{33}. While providing some insight into the magnetization processes which generate the magnetostriction, the results are of potential value for practical applications.

EXPERIMENTAL TECHNIQUES

A furnace capable of reaching ~1000 °C was situated between the 8 in. diameter poles of an electromagnet to generate annealing fields, H_a, ~1000 kA m^{-1}. The sample enclosure was evacuated and repeatedly flushed with argon, before filling to a pressure of ~1/2 atm. Samples were wrapped in tantalum foil to minimize oxidation. Cooling rates of ~25 °C/min were used.

Commercial grade samples of material were prepared by a free float zone process, ~140 mm long and ~6 mm diameter, grain orientated with the [11$\bar{2}$] axes parallel to the rod axis. Polishing and etching were used to reveal grain structure at each end for the purposes of orientation. Gross misorientation of grains along the lengths of the samples were detectable with a nondestructive scanning technique.[5] The nominal compositions of each sample provided by the manufacturers are given in Table I, together with their individual heat treatments and magnetic annealing conditions. Sample "C" was cut into four equal lengths C1,...,C4. Prior to treatment, these four sections did not display any significant differences in magnetostrictive behavior.

Room temperature magnetostrictive strains in DC fields (≤120 kA m^{-1}) were measured using strain gauges with fields, applied uniaxial stresses, and strain measurement directions along the [11$\bar{2}$] direction of the oriented grains. Data were differentiated numerically to obtain values for the *d* coefficients.

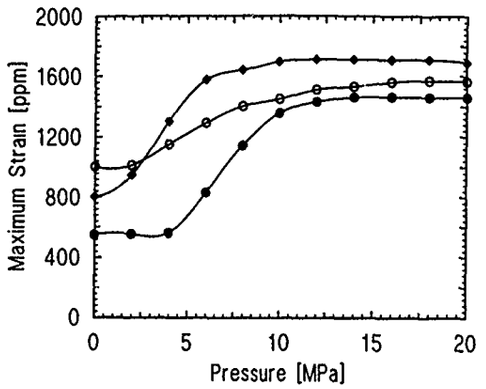

FIG. 1. Sample A: pressure dependence of the maximum strains at 120 kA m^{-1} for material composition $Tb_{0.3}Dy_{0.7}Fe_{1.95}$ as received (●), magnetically annealed with H_a applied parallel to the [110] axis (○) and [11$\bar{1}$] axis (♦).

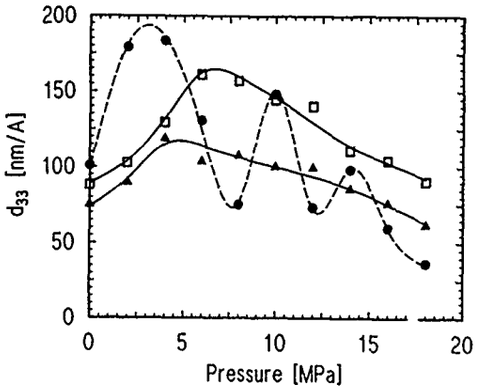

FIG. 3. Sample B: pressure dependence of the d coefficient for as received (□), magnetically annealed with H_a applied parallel to the [110] axis (▲) and [11$\bar{1}$] axis (●).

RESULTS

For *sample A*, the maximum strains at 120 kA m^{-1} and maximum d coefficients as functions of pressure in "as received" material are compared with results after the sample was magnetically annealed twice, once with H_a applied approximately parallel to the [111] direction and then along the [110] direction (Figs. 1 and 2). Both annealing directions improve λ_{max} slightly at low pressures but the response of d_{33} to magnetic annealing is more pronounced than λ_{max}. An exceptionally large $d_{33}\sim260$ nm A^{-1} is observed with a prestress of 10 MPa when annealed with H_a along the [111] axis. *Sample B*, having the same history of treatment as sample A, exhibits the same kind of response, viz., a small increase in λ_{max} at low pressures after magnetic anneal, regardless of the direction of H_a. The change in d-coefficient response is far greater, with $d_{33}\sim190$ nm A^{-1} at ~3 MPa (Fig. 3) but in this sample an oscillatory variation of d_{33} with pressure is very strong after applying H_a along the [111] axis. Similar oscillations can be seen in the results from sample A, but much weaker.

Sample C1 and *C2* received identical heat treatments except the annealing field was not applied to C2. The purpose of this procedure was to identify how much of the subsequent magnetostrictive response was due to the application of H_a rather than thermally induced compositional changes. The effects of the magnetic anneal over and above the thermal effects are clear. Heat treatment alone (Fig. 4) moves the peak in the d_{33} to a lower pressure (~8 MPa) but the magnitude is not increased; magnetic annealing doubles the maximum d coefficient and reduces the required prestress from 14 to 3 MPa. *Sample C4* shows an almost identical change in behavior to sample C1 (Fig. 5).

DISCUSSION

It is observed that magnetic annealing has a more marked effect on the pressure dependent behavior of d_{33} than on λ_{max}. A reduction in uniaxial prestresses to achieve maximum d_{33} indicates that magnetic annealing introduces extra anisotropy which assists in the preferential distribution of moments along the [111] axis prior to the application of a magnetizing field.[6] Magnetization then proceeds by the ma-

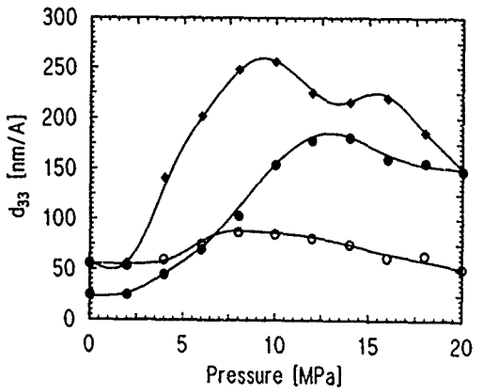

FIG. 2. Sample A: pressure dependence of the d coefficient for as received (●), magnetically annealed with H_a applied parallel to the [110] axis (○) and [11$\bar{1}$] axis (♦).

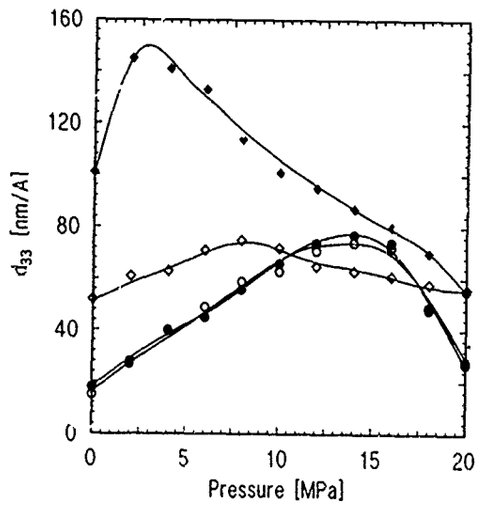

FIG. 4. d_{33} vs pressure for the composition $Tb_{0.32}Dy_{0.68}Fe_{1.95}$ thermally annealed sample C2 (◇) or magnetically annealed sample C1 (♦), compared with the "as received" performances for C1 (●) and C2 (○).

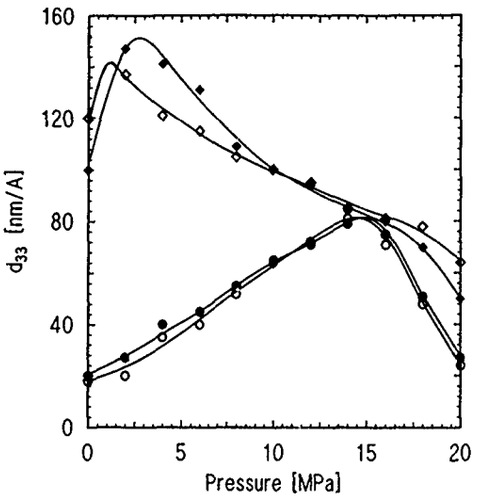

FIG. 5 d_{33} vs pressure for the composition $Tb_{0.32}Dy_{0.68}Fe_{1.95}$ magnetically annealed samples C1 (♦) and C4 (◇) compared with performances prior to annealing, C1 (●) and C4 (○).

jority of moments rotating away from the [111] direction towards the [11$\bar{2}$] axis and the corresponding magnetostrictive response, as gauged by the magnitude of d_{33}, is maximized. The maximum strain λ_{max} depends on the final state of magnetization rather than the processes through which it is achieved. Hence the magnitude of λ_{max}, as expected, is virtually independent of anisotropy induced by magnetic annealing (Table II).

In addition to the initial distribution of moments amongst the ⟨111⟩ axes, the subsequent magnetization processes which determine the magnitude of d_{33} are also influenced by the shapes of the anisotropy surfaces.[7] The combined effects of three anisotropies, mangetocrystalline and induced anisotropies from the application of stress or magnetic annealing, will regulate the surface shape. When uniaxial pressure is applied the balance of the three energy components is perturbed and the surface modified. It is considered that the oscillations in d_{33} as a function of pressure in samples A and B after magnetic annealing originate not only from the initial distribution of moments but from pressure induced periodic undulations in the energy surfaces.

The effects of magnetic annealing could be of value for practical purposes (for example, to reduce the level of prestress required to gain maximum d coefficient) provided the response of any sample to post production processing can be predicted. In the present work, no correlation is evident between the pre- and post-annealed d coefficients. However, the magnitude of the prestress required to achieve an optimum d coefficient is lower for material containing a higher Tb:Dy ratio (Table II).

In the absence of an annealing field, changes occur at elevated temperatures causing, for instance, a reduction of the bias pressure for optimum d coefficient in sample C2. Compositional changes such as the diffusion of RE ions from the grain boundaries maximize interatomic magnetoelastic coupling,[2] which enhances the pressure sensitivity. Only if the magnetoelastic coupling is strong enough will a sample of material be susceptible to magnetic annealing. Then, in cooling from T_c to room temperature, the annealing field retains the moments along a particular ⟨111⟩ direction and the maximum macroscopic contraction will develop along the aligned [11$\bar{2}$] grain axes as the spontaneous magnetostriction develops. This lowers the free energy and after annealing is completed the contraction will then be retained, as observed in practice, until sufficient energy is supplied to redistribute the moments among all the ⟨111⟩ axes. In other words, magnetic annealing could be magnetostrictively driven.

TABLE II. Increases in the d coefficient (d_{33}) and maximum strains at 120 kA m^{-1} (λ_{max}) observed in each sample and maximum d coefficients measured with optimum applied stress (σ) and field (H)

Sample	d_{33} (%)	λ_{max} (%)	max. d_{33} (rm A^{-1})	Opt. σ (MPa)	Opt. H (kA m^{-1})
A	44	17	260	9.5	12
B	18	~0	190	3.0	15
C1	81	~0	145	3 0	19
C4	73	~0	135	1.5	11

CONCLUSIONS

The d coefficient is particularly responsive to magnetic annealing as seen in both its magnitude and the optimum pressure bias. The thermal element of a magnetic anneal process is important in controlling the composition, which maximizes the magnetoelastic coupling. A spontaneous magnetostrictive deformation that accompanies magnetic annealing could be the origin of the extra anisotropy which subsequently causes moments to align preferentially along the field anneal direction.

Tatsuru Namikawa and Yohtaro Yamazaki
Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227, Japan

Electromagnetic waves generated from the magnetostrictive vibrations of amorphous ribbons under nonuniform bias fields were investigated. The sample ribbon 80 mm in length was placed on a plastic support board where both edges of the ribbon were free. In a uniform bias field generated by a Helmholtz coil, four resonance peaks of 27, 54, 81, and 107 kHz were detected. The nonuniform magnetic fields were generated by single-pole magnetic heads. Two single-pole magnetic heads with 3 mm spacing between the ribbon were moved along the ribbon. When the heads were located at 10 and 70 mm from an edge of the ribbon, the frequency of the detected response was 54 kHz, i.e., the detected response was the second resonance peak. The other resonance peaks (81, 107, and 129 kHz) could also be separated by adjusting the positions of the heads. Therefore, the electromagnetic response of the magnetostrictive vibrations of amorphous ribbons could be controlled by applying appropriate nonuniform bias magnetic fields. From the results, it is suggested that a magnetostrictive amorphous ribbon not only sends one bit data but also sends multiple bit data with the aid of bias magnetic fields.

INTRODUCTION

Some amorphous magnetic ribbons have large magnetostrictive coefficients and they have been applied to many devices.[1] When an ac magnetic field is applied to a magnetostrictive ribbon with a uniform dc magnetic field, a mechanical vibration is induced. Through the analysis of mechanical resonance, the magnetomechanical coupling factor k of the material is determined.[2–8] The vibrations have many resonance points which depend on the sample's shape and induce electromagnetic waves which can be detected by an antenna. It is expected that, through amorphous ribbons, we can send multiple bit data by separating the resonance mode.

In this study, we observe the resonance peaks of amorphous ribbons for uniform and nonuniform bias magnetic fields, to investigate the separation of the vibration modes.

EXPERIMENT

The schematic of the experimental setup is presented in Fig. 1. An exciting coil of 34 mm in diameter and 200 turns was placed 35 mm apart from the detecting coil. The signal from the sample was detected by a figure-eight coil, so as to eliminate the exciting signal. The measurement was made in the frequency range from 10 to 200 kHz. The exciting current was from 44 to 2 mA. The exciting coil generated ac magnetic fields of about 3.0 to 0.2 Oe rms, at the center of the coil.

The figure-eight coil consists of two rectangles with a size of 80×25 mm^2 and 10 turns. The signal from the figure-eight coil was measured by a network/spectrum analyzer. The wave form and phase of the exciting voltage were monitored by an oscilloscope.

A Metglas™ 2826MB ($Fe_{40}Ni_{38}Mo_4B_{18}$) (Refs. 6 and 9) amorphous ribbon with size of 80×12 mm^2 and thickness of 0.03 mm was used, as a sample. The sample ribbon was as cast and placed on a plastic support board. The sample ribbon was not fixed and both edges were free. The position of the ribbon was adjusted so that an edge of the ribbon was located near the center of the figure-eight coil. In order to apply a uniform bias field to the sample ribbon, a Helmholtz coil was added.

Figure 2 shows the schematic diagram for generating nonuniform field patterns by using single-pole magnetic heads. The single-pole heads were made of soft steel plates $50\times15\times0.3$ mm^3, and a copper wire of 0.2 mm was wound 200 turns. The space between the single-pole heads and amorphous ribbon was 3 mm. The magnetic field from the single-pole head was 6 Oe at the surface of the amorphous ribbon.

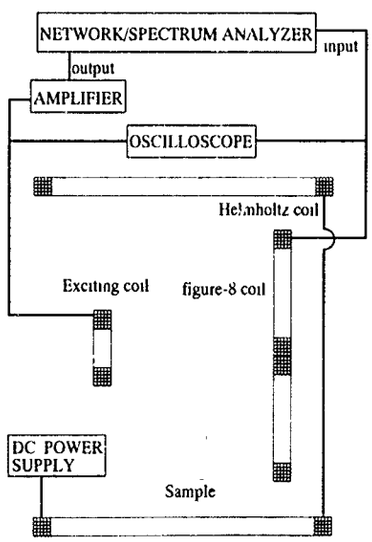

FIG. 1. Schematic diagram of experimental apparatus.

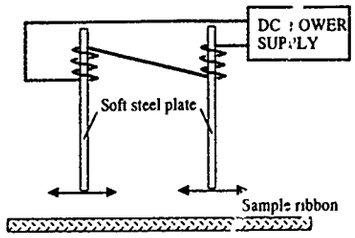

FIG. 2. Schematic diagram for generating nonuniform field patterns by using single-pole magnetic heads.

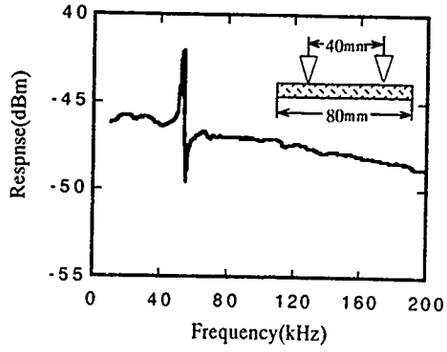

FIG. 4. Power spectrum with a uniform magnetic field for a confined amorphous ribbon. Two positions of the ribbon were fixed to the support board by using a pair of thin plastic plates.

RESULTS AND DISCUSSION

Figure 3 shows the power spectrum measured with a uniform magnetic field of 4 Oe. The frequencies of the peak points were 27, 54, 81, and 107 kHz, and correspond to the first, second, third, and fourth harmonics, respectively. The peak observed at 116 kHz was expected to be a resonance of the transverse mode. We use the relationship between the resonance frequency and the length of the media as

$$f_n = nv/(2l), \tag{1}$$

where f_n is the nth resonance frequency, l is the length of the media, and v is the velocity of sound. We calculate the resonance frequencies from the first to the fourth as 27, 54, 81, and 107 kHz by using Eq. (1) and $v = 4320$ m/s.

In other amorphous ribbons, Metglas 2605SC ($Fe_{81}B_{13.5}Si_{3.5}C_2$),[10] 2605S-2 ($Fe_{78}Si_9B_{13}$),[10] and 2605CO ($Fe_{67}Co_{18}B_{14}Si_1$),[11] the power spectra did not generate sharp peaks provided the sample ribbons were as cast.

Figure 4 shows the power spectrum with a uniform magnetic field of 4 Oe, where the two positions of 20 and 60 mm from an edge of the ribbon were fixed to the support board by using a pair of thin plastic plates (0.2 mm thick). Only one peak of 54 kHz was detected in this case. Considering Eq. (1) and the result of Fig. 4, this peak is expected to be the second harmonic resonance, and the fixing positions correspond to the nodes for the vibration. Therefore, other harmonic modes were suppressed.

Figure 5 shows the separation of the resonance peaks using nonuniform magnetic fields. The power spectrum without peaks, shown as A in the figure was obtained when no uniform field nor nonuniform field were applied. The following results were obtained with nonuniform magnetic fields. Curves B–E were obtained by using a pair of single-pole magnetic heads. The spaces between the heads are shown in the figure. The distances from the edges of the ribbon to the heads are equal for both ends. The frequencies of the highest peaks for the head distances and polarities were 54, 81, 107, and 129 kHz for 60, 30, 40, and 54 mm, respectively. Curves B and D were obtained with magnetic heads having different polarities. The peaks in curves B, C, and D correspond to the

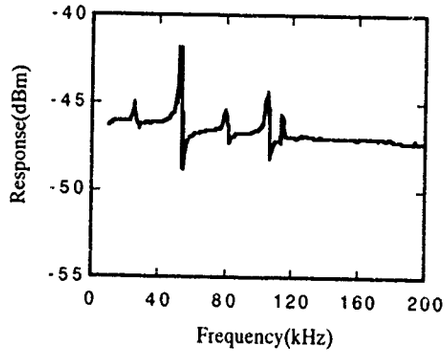

FIG 3 Power spectrum of magnetostrictive vibrations with a uniform magnetic field.

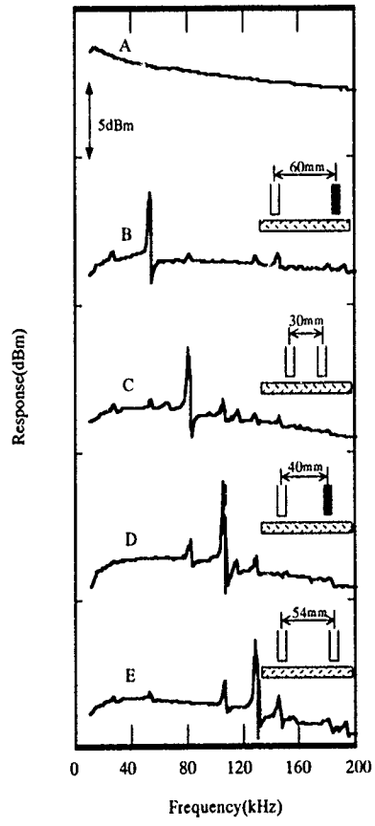

FIG. 5. Separation of resonance peaks, A: without magnetic field, B–E: nonuniform magnetic fields are applied with magnetic heads. Magnetic polarities of the heads are indicated by black and white.

second, third, and fourth resonance peaks in Fig. 3. The peak in curve E is not observed in Fig. 3, however, we estimate the fifth harmonic frequency as 135 kHz using Eq. (1). Therefore the peak can be assigned to the fifth resonance. It is noted that the intensities of the highest peaks are almost equal, compared with Fig. 3.

The power spectra that we obtain by the measurements relate to the magnetomechanical coupling factor k of the material. It is expected that more than six resonance peaks may be detected when the magnetomechanical coupling factor of sample ribbons is increased.

CONCLUSIONS

The relationship between the resonances in the magnetostrictive vibration of amorphous ribbons and bias magnetic field patterns was investigated. The first, second, third, and fourth harmonic peaks were detected in an amorphous ribbon 80 mm in length and 12 mm in width, with a uniform bias field. Specific resonance peaks were detected with nonuniform magnetic bias patterns which were generated with a pair of single-pole magnetic heads. Therefore, the response of the harmonics frequencies could be controlled by applying appropriate nonuniform bias magnetic fields. From the result, it is suggested that a magnetostrictive amorphous ribbon not only sends one bit data but also sends multiple bit data with the aid of bias magnetic fields.

From AIP Press
in cooperation with the American Vacuum Society

AVS Classics Series in Vacuum Science and Technology

Series editor, H. Fredrick Dylla, CEBAF, Newport News, VA, and College of William and Mary, Williamsburg, VA

Vacuum Technology and Space Simulation
D.J. Santeler, D.H. Holkeboer, D.W. Jones, and F. Pagano

While specific projects have changed in the 30 years since this book was first published, the need for large, complex vacuum facilities has not. And despite new developments in pumping, measurement, and outgassing, this book will remain, for many years to come, the standard of practical vacuum operation.

1993, 350 pages, illustrated, ISBN 1-56396-123-7, paper
$35.00 **Members $28.00**

Field Emission and Field Ionization
Robert Gomer

This authoritative work was based on four lectures presented at Harvard University in 1958. When it was written, field emission was one of the few techniques available for surface studies, and the attainment of ultra-high vacuum was a little-known art. Though more sophisticated treatments have been developed, Gomer's pioneering work remains extremely relevant.

1993, 200 pages, illustrated, ISBN 1-56396-124-5, paper
$35.00 **Members $28.00**

Handbook of Electron Tube and Vacuum Techniques
Fred Rosebury

This handbook was originally prepared so that workers would have a single source for learning the procedures and materials needed to construct tubes and other evacuated devices. Even now, as space and high-vacuum research yield new information daily, much of the subject matter in this seminal work—such as properties of materials—are as cogent as they were in 1964 when the book was first published.

1993, 600 pages, illustrated, ISBN 1-56396-121-0, paper
$35.00 **Members $28.00**

The Physical Basis of Ultrahigh Vacuum
P.A. Redhead, J.P. Hobson, and E.V. Kornelsen

Written 25 years ago, this book explains both the design and use of UHV systems and components, as well as the underlying physical principles on which the performance of the equipment depends. The close association of these underlying physical principles with the practical problems inherent in UHV equipment makes this a fundamental resource, still sought after by today's researchers.

1993, 500 pages, illustrated, ISBN 1-56396-122-9, paper
$35.00 **Members $28.00**

Ionized Gases
A. von Engel

Though based on the author's lectures for undergraduates at Oxford, this classic 1955 work is also a valuable resource today for practitioners in atomic physics, astrophysics, spectroscopy, and, most especially, semiconductors. Researchers and graduate students will find that von Engel's ideas hold up remarkably well.

1994, 344 pages, ISBN 1-56396-272-1, illustrated, paper
$35.00 **Members $28.00**

Vacuum Sealing Techniques
Alexander Roth

This volume presents numerous techniques developed in the early '60s for the construction of vacuum seals, providing critical insights into the design and construction of the vacuum system's constituent parts and the proper assembly of the system. Extensively researched, this work covers a variety of sealing techniques and design concepts that are relevant to this day.

1994, 860 pages, ISBN 1-56396-259-4, illustrated, paper
$35.00 **Members $28.00**

Basic Data of Plasma Physics: The Fundamental Data on Electrical Discharges in Gases
Sanborn C. Brown

This 1966 reference work is a compilation of some of the most important plasma physics articles published during the late 1950s and the early 1960s. It offers a wealth of useful information on elastic-collision and charge-transfer cross sections, mobility and diffusion, electron attachment and detachment, and recombination. Numerous fundamental principles make this a much- consulted handbook on the physical phenomena, measurements, and properties of plasma physics.

Fantastic Voyages

Learning Science Through Science Fiction Films

Leroy W. Dubeck, Suzanne E. Moshier, and Judith E. Boss

By revealing the facts behind the fiction of some of the finest sci-fi films, ***Fantastic Voyages*** offers a novel approach to teaching science—using science fiction to illustrate fundamental concepts of physics, astronomy, and biology.

Each film scene depicts a scientific principle, or its violation, reinforcing concepts that are taught in more traditional ways. The chapter Electricity and Magnetism discusses the use of computers in *Blade Runner*. Under astronomy, *2001* is examined as it relates to ancient astronauts. In the chapter Evolution, *Planet of the Apes* is studied in detail.

Helpful end-of-chapter exercises, together with more than 20 movie stills, further aid readers to grasp the technical material. Nonscience majors, science fiction enthusiasts, and film buffs will find this work both enjoyable and instructive.

1993, 400 pages, ISBN 1-56396-195-4, paper, illustrated

The Physics of Golf

Theodore P. Jorgensen

In ***The Physics of Golf***, you'll learn how to apply the principles of dynamics and energy to perfect your golf stroke, to choose the right clubs, and to make the handicap system work optimally. Using stroboscopic photographs and an ingenious mathematical calculation, the author shows you how small changes in your swing can increase the distance the ball travels.

This engaging book provides many more tips concerning the critical components of a good swing, helping you to play better and to get more enjoyment out of your round.

Time Machines

Time Travel in Physics, Metaphysics, and Science Fiction

Paul J. Nahin

Time Machines takes you on an exhilarating journey through the intriguing theories of scientists and the far-flung imaginations of writers. Explore the ideas of time travel from the first account in English literature — Samuel Madden's 1733 *Memoirs of the Twentieth Century* — to the latest theories of physicists such as Kip Thorne and Igor Novikov.

This accessible work covers a variety of topics including the history of time travel in fiction; the fundamental scientific concepts of time, spacetime, and the fourth dimension; time-travel paradoxes; the speculations of Einstein, Richard Feynman, Kurt Gödel, and others; and much more.

1993, 512 pages,ISBN 0-88318-935-6, cloth, illustrated

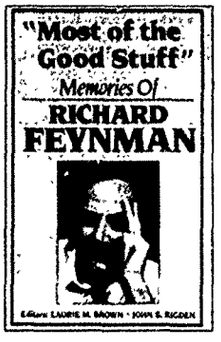
"Most of the Good Stuff"

Memories of Richard Feynman

Laurie M. Brown and John S. Rigden

Prominent physicists such as John Wheeler, Freeman Dyson, Hans Bethe, Julian Schwinger, Murray Gell-Mann, David Pines, and others offer intimate reminiscences of their colleague and perceptive explanations of Feynman's trail-blazing work. These essays uncover the precocious undergraduate, the young scholar at Cornell, the theoretician in his prime at Caltech, and the mature teacher and mentor.



Highlighting both the charm and the brilliance of Feynman, ***"Most of the Good Stuff"*** is an engrossing collection for enthusiasts—scientists and nonscientists alike—awed and entertained by one of the century's greatest minds.

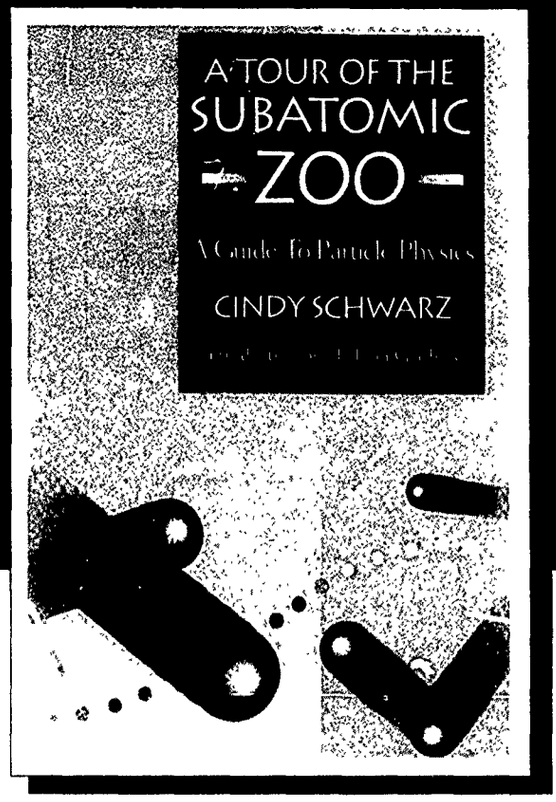
A TOUR OF THE SUBATOMIC ZOO

A Guide to Particle Physics

Cindy Schwarz, *Vassar College*



"A great little book, and if every physics textbook were like this, physics classrooms would be crowded."

—Scitech Book News

With hardly a mathematical formula, Ms. Schwarz clearly explains the substance of elementary particle physics. The book guides readers through the subatomic "zoo," populated by some of the most dramatic discoveries of modern science—notably, quarks, leptons, and the basic forces that govern their interactions.

Most important, this tour is conducted in terms that are easily understood—even by those who have no prior particle physics background. Each chapter in this book begins with an overview of concepts and ends with a summary and self-tests to help readers gauge their understanding.

If you're involved in teaching science to the non-scientist, think about using this book. It's been used successfully to introduce future lawyers, politicians, and parents to the ideas, terminology, and techniques of high energy physics and it's given them a unique historical perspective on the field.

TRANSFER OF COPYRIGHT AGREEMENT

Copyright to the unpublished and original article, including copyright to the abstract forming part thereof, entitled

_____

submitted by the following author(s) (names of all authors)_____

_____

is hereby transferred to American Institute of Physics (AIP) for the full term thereof throughout the world, BUT SUBJECT to the following rights reserved to the author(s) and to acceptance of the article for publication in

_____
Name of Journal

AIP shall have the right to publish the article in any medium or form, or by any means, now known or later developed.

AIP shall have the right to register copyright in the article and the accompanying abstract in its name as claimant, whether separately or as part of the journal issue or other medium in which such work is included.

The author(s) reserve the following rights:

(1) All proprietary rights other than copyright, such as patent rights.
(2) The right, after publication by AIP, to grant or refuse permission to third parties to republish all or part of the article or translations thereof. In the case of whole articles, such third parties must obtain AIP's written permission as well. However, such permission will not be refused by AIP except at the direction of the author. AIP may grant rights with respect to journal issues as a whole.
(3) The right, after publication by AIP, to use all or part of the article and abstract in compilations or other publications of the author's own works, and to make copies of all or part of such material for the author's use for lecture or classroom purposes.
(4) If the article has been prepared by an employee within the scope of his or her employment, the employer reserves the right to make copies of the work for its own internal use. If the article was prepared under a U.S. Government contract, the government shall have the rights under the copyright to the extent required by the contract.

The author(s) agree that all copies of the article or abstract made under any of the above reserved rights shall include a copyright notice in the AIP's name. The author(s) represent and warrant that the article is original with them, that it does not infringe any copyright or other rights in any other work, or violate any other rights, and that the author(s) own the copyright in it or are authorized to transfer it. If each author's signature does not appear below, the signing author(s) represent that they sign this agreement as authorized agents for and on behalf of all the authors, and that this agreement and authorization is made on behalf of all the authors.

AMERICAN INSTITUTE OF PHYSICS

500 Sunnyside Boulevard, Woodbury, NY 11797-2999

The American Institute of Physics is a not-for-profit membership corporation chartered in New York State in 1931 for the purpose of promoting the advancement and diffusion of the knowledge of physics and its application to human welfare. Leading societies in the fields of physics, astronomy, and related sciences are its members.

The Institute publishes its own scientific journals as well as those of its member societies; publishes both technical and general interest books; provides abstracting and indexing services; provides on-line database and e-mail services; disseminates reliable information on physics to the public; collects and analyzes statistics on the profession and on physics education; encourages and assists in the documentation and study of the history and philosophy of physics; cooperates with other organizations on educational projects at all levels; and collects and analyzes information on Federal programs and budgets.

APPLIED PHYSICS LETTERS: Current Table of Contents

Applied Physics Letters, a companion publication to the *Journal of Applied Physics*, is published weekly by the American Institute of Physics. Its letters are timely, short reports devoted to important new findings in applied physics. The contents list below is from a recent issue.

APPLIED PHYSICS LETTERS

Vol 65, No 17, 24 October 1994

CODEN APPLAB ISSN 0003-6951

OPTICS

2121 **Single-beam time-resolved Z-scan measurements of slow absorbers** — L C Oliveira S C Zilio

2124 **Bright red light-emitting organic electroluminescent devices having a europium complex as an emitter** — Junji Kido Hiromichi Hayase Kenichi Hongawa Katsutoshi Nagai Katsuro Okuyama

2127 **Selective ablation of a hydrogenated amorphous silicon thin layer by the second-harmonic radiation of a transversely excited atmospheric CO_2 laser** — Tetsumi Sumiyoshi Yutaka Hiromiya Akira Shiratori Minoru Obara Katsunori Ishii

2130 **Novel tunable semiconductor lasers using continuously chirped distributed feedback gratings with ultrahigh spatial precision** — H Hillmer H -L Zhu A Grabmaier S Hansmann H Burkhard K Magari

FLUIDS, PLASMAS, AND ELECTRICAL DISCHARGES

2133 **Repetitively pulsed relativistic klystron amplifier** — Jerrold S Levine Bruce D Harteneck

CONDENSED MATTER (STRUCTURE, MECHANICAL AND THERMAL PROPERTIES)

2136 **Metallic glass formation in highly undercooled $Zr_{41.2}Ti_{13.8}Cu_{12.5}Ni_{10.0}Be_{22.5}$ during containerless electrostatic levitation processing** — Y J Kim R Busch W L Johnson A J Rulison W K Rhim

2139 **Direct growing of lightly doped epitaxial silicon without misfit dislocation on heavily boron-doped silicon layer** — Ho-Jun Lee Chang-Soo Kim Chul Hi Han Chioong Ki Kim

2142 **Fabricating nanoscale structures on Au surface with scanning tunneling microscope** — K Besocke S Hashimoto

2145 **Two kinds of nitrogen atoms in nitrogen-substituted, highly crystalline graphite prepared by chemical vapor deposition** — T Matsui M Yudasaka R Kikuchi Y Ohki S Yoshimura

2148 **Enhanced confinement of electrons at room temperature using a superlattice reflector** — D Campi C Rigo C Caccia tore H -C Neitzert

2151 **Three-dimensional electrostatic potential, and potential-energy barrier, near a tip-base junction** — Li-Hong Pan Thomas E Sullivan Vallorie J Pendler Paul H Cutler Nicholas M Miskovsky

2154 **Fabrication of a periodically domain-inverted structure in $LiNbO_3$ thin film by a domain-transfer technique** — Hiroshi Momii Kazumi Kawamoto Kenchi Ito

2156 **New synthetic route to the formation of fullerene superconductors** — J H Hwang C Y Mou H S Sheu Y Wang M K Wu

SEMICONDUCTORS

2159 **$Ga_xIn_{1-x}As/AlAs$ resonant tunneling diodes grown by atmospheric pressure metalorganic chemical vapor deposition** — B P Keller J C Yen S P DenBaars U K Mishra

2162 **Crystalline phases of II-VI compound semiconductors grown by pulsed laser deposition** — W P Shen H S Kwok

2165 **Low resistance ohmic contacts on nitrogen ion bombarded InP** — F Ren S J Pearton J R Lothian S N G Chu W K Chu R G Wilson C R Abernathy S S Pei

2168 **Low temperature mobility limiting defects in CdTe/CdMnTe multi-quantum-well structures** — M Godlewski C I Harris J P Bergman B Monemar A Waag

2171 **Preparation of crystallographically aligned layers of silicon carbide by pulsed laser deposition of carbon onto Si wafers** — L Rimai R Ager W H Weber J Hangas B D Poindexter

2174 **Hydrogenation of multiple-quantum-well optical-modulator structures** — T K Woodward, J E Cunningham, W Y Jan A Kastalsky

2177 **Electrical properties of thermal oxide grown using dry oxidation on *p*-type 6H-silicon carbide** — Dev Alok, P K. McLarty, B J Baliga

2179 **Negative differential conductance frequency resonances in *X* valley superlattice minibands** — A Sibille, J F Palmier H Wang R Planel

2182 **Nanocrystal size modifications in porous silicon by preanodization ion implantation** — L. Pavesi, G Giebel, F Ziglio, G Mariotto F Priolo, S U Campisano, C Spinella

2185 **Growth and characterization of thallium- and gold-doped $PbSe_{0.78}Te_{0.22}$ layers lattice matched with BaF_2 substrates** — Patrick J McCann Srinath K Aanegola, John E Furneaux

2188 **Nondestructive mapping of carrier concentration and dislocation density in n^+-type GaAs** — D C Look, D C Walters, M G Mier, J R Sizelove

2191 **Spectroscopy of hydrogen-related complexes in GaP:Zn** — M D McCluskey, E E Haller, J Walker, N M Johnson

2193 **Optical monitoring of the growth of heavily doped GaAs by chemical beam epitaxy and of the *in situ* etching of GaAs using CBr_4** — T B Joyce T J Bullough, T Farrell

2196 **Design of high-performance quantum well electron transfer modulators via self-consistent modeling** — Jin Wang J E Zucker, J P Leburton, T Y Chang, N J Sauer

2199 **Observation of sulfur-terminated GaAs(001)-(2×6) reconstruction by scanning tunneling microscopy** — Shiro Tsukamoto, Nobuyuki Koguchi

2202 **Measurement of nonuniform distribution of strain in InGaAs/GaAs quantum wires** — Yu-Pei Chen, Jason D Reed, William J Schaff, Lester F Eastman

2205 **Carbon doping of AlAs using CCl_4 and CBr_4 during growth by metalorganic molecular-beam epitaxy** — C R Abernathy, J D MacKenzie W S Hobson, P W Wisk

2208 **Electrically active subthreshold damage in Si ion implanted with Si, Ge, and Sn** — P Kringhøj, J S Williams, C Jagadish

2211 **Determination of the GaN/AlN band offset via the (-/0) acceptor level of iron** — J Baur, K Maier, M Kunzer, U Kaufmann, J Schneider

2214 **Conduction-band engineering in piezoelectric [111] multiple quantum well *p-i-n* photodiodes** — J L Sanchez-Rojas A. Sacedon F Calle E Calleja E Muñoz

2217 **Selective epitaxial growth of GaInP by low-pressure metal-organic chemical-vapor deposition using ethyldimethylindium as in source** — Shih-Hsiung Chan Simon Ming Sze Chun-Yen Chang, W. I Lee

2220 **Magnetron sputter epitaxy of Si_mCe_n/Si(001) strained-layer superlattices** — P Sutter, C Schwarz E Müller V Zelezny S Goncalves Conto, H von Kanel

2223 **Bandwidth enhanced metal-semiconductor-metal photodetectors based on backgated *ip* structures** — E Greger, K Reingruber P Riel G H Döhler, J Rosenzweig, M Ludwig

2226 **Infrared absorption of holes in a parabolic quantum well** — M Sundaram, S J Allen, Jr M R Geller, P F Hopkins, K. L Campman A C Gossard

2229 **Oxidation of silicon nitride prepared by plasma-enhanced chemical vapor deposition at low temperature** — Wen-Shiang Liao Chi-Huei Lin, Si-Chen Lee

SUPERCONDUCTORS

2232 **Insulating boundary layer and magnetic scattering in $YBa_2Cu_3O_{7-\delta}$/Ag interfaces over a contact resistivity range of 10^{-6}–10^{-3} Ω cm²** — S C Sanders S E Russek, C C Clickner, J W Ekin

2235 **CUMULATIVE AUTHOR INDEX**
